CHAPTER 75

Infections Related to Craniofacial Surgical Procedures

Marc A. Mazade

Craniofacial surgeons are operating more frequently in recent years in the management of traumatic injury, neoplasia, and syndromic and nonsyndromic craniofacial dysostosis, owing in part to the earthquakes in Haiti and Chile in 2010 that contributed to the need for craniofacial reconstructive procedures.[18] The incidence of associated craniofacial surgical infections was 14.7 percent in one study and 8.1 percent in another, but it varies greatly and may range from 3 to 45 percent, depending on the number of procedures undertaken during a single anesthesia, surgical duration, and the structures involved.[9,11] A review published in 2005 demonstrated a rate of 3.2 infections per 100 craniofacial surgical procedures and found that surgical duration longer than 7 hours, closure of skin under tension, use of bovine pericardium, and the presence of more than four surgeons in the operating

suite were common risks for development of infection.[28] Determining when an infection has occurred is difficult. The overall facial appearance of the child may be so altered by the surgical intervention and postoperative swelling that even parents may not recognize that infection has occurred. Diagnostic needle aspiration may be helpful. Because infections tend to be caused by bacteria that reside in the sites through which incisions and osteotomies are performed, the main culprits are skin, paranasal sinus, and oropharyngeal flora. Each additional site that is surgically violated increases the risk for development of an infection. Infections include cellulitis and dehiscence of the wound, infection of subgaleal fluid, osteomyelitis, focal soft tissue abscesses, epidural abscesses, and septicemia.[9,27,28] Exposure of harvested bone and use of metal plates, special cements, distraction pin systems, and wires render infection treatment decisions difficult, so follow-up plays a greater role in management of related infections than in management of simple surgical site infections. Routes of antibiotic administration and duration of antibiotic therapy are poorly established. Most procedures have required extensive preoperative planning, and what is done may not be so easily undone. The infectious diseases consultant must be prepared to engage in an ongoing dialogue with the surgeon and the patient's family, determining what can be removed and at what cost, providing objective feedback about the success of the treatment to that point, and declaring, when needed, that a failure of medical therapy has occurred. Stating dogmatically that all devitalized bone and foreign material must be removed will, in all likelihood, cause the surgeon to delay requesting consultation when infectious diseases services are again needed.

PROCEDURES AND INFECTIONS

Some children require palatal reconstruction, others need distraction osteogenesis by mandibular distraction pin device systems for mandibular hypoplasia.[16] Some require advancement of large portions of the face. One less commonly performed procedure to correct midfacial retrusion is the frontofacial monobloc advancement.[20] This procedure involves detachment and advancement of the entire facial bony mask and commonly requires a large frontal craniotomy, the bone from which may be shaped to complete the repair or used as needed to form a suitable foundation to which the advanced monobloc can be secured. Osteotomies are performed along the lower portion of the frontal bone and posteriorly along the roof of the orbits, along the lateral and medial inferior walls of the orbits, and through the zygomatic arches, with subsequent pterygomaxillary disjunction. A frontoethmoidal osteotomy divides the posterior portion of the nasal septum to free the monobloc so that it can be advanced and secured in place by wiring it anteriorly to a slightly fore-tilted strip of frontal bone and stabilizing it laterally with wired-in strips of calvarial bone grafts to bridge gaps in the zygomatic arches. Bone blocks in the pterygomaxillary area help to hold the maxillary portion forward. The temporary dead space created in the anterior cranial fossa is problematic in some patients.[27] This procedure is associated with an inherent risk for developing meningitis, which is associated less frequently with the extracranial procedures described later, although meningitis still may occur.[24] An alternative procedure that seeks to avoid entering sinus cavities and the cranium is the subcranial Le Fort III osteotomy.[12,20] Exposure is provided through a coronal incision with distraction of the soft tissues of the forehead. Osteotomies free part of the medial, lateral, and inferior walls of the orbit and the nasal bridge, and the remainder of the midface bloc is freed by pterygopalatine disjunction and osteotomies of the zygomatic arch and posterior nasal septum. Thus, only the midface bloc is brought forward, and interposition grafts, hydroxyapatite, microplates, and wires secure the bloc in the advanced position. As in the frontofacial advancement, split calvarial bone grafts bridge the space in the zygomatic arches. A Le Fort I osteotomy is an isolated maxillary advancement procedure that might additionally be used to change the position of the upper teeth.[12,15,20]

Some cases of Treacher Collins syndrome require the Integrale (simultaneous midfacial and mandibular osteotomies).[20] In this complicated procedure requiring a tracheostomy, the midface osteotomies exclude the temporal, lateral walls of the orbits from the advanced bloc. In addition, osteotomies shaped like a C or inverted V through the mandibular rami with placement of the interposition bone grafts and wiring provide advancement of the mandible. Split calvarial bone grafts subsequently reestablish the zygomatic arches.

Reconstructive materials include bone autograft and solvent-treated allograft, titanium plates, and alloplasts such as polymethyl methacrylate and hydroxyapatite cements, some of which readily accept bone ingrowth and wires. New materials are in development. In an effort to limit postoperative infection, antibiotics such as tobramycin may be mixed into hydroxyapatite cements, which are released into the surrounding field within the first 24 hours of placement.[17]

In many instances, infection permeates the entire operative field.[11] Donor bone graft sites may be involved in some instances. Bacteria may infect the wound or soft tissue area, may spread by contiguous extension through cortical bone during long periods of contact, or may extend through osteotomies that have disrupted the integrity of the periosteum and cortical bone barriers. Additionally, surgical alteration of the local blood supply to the cranial bones through disruption of medullary channels and removal of the adherent periosteum, as well as the presence of hardware required to secure the bony structures in their new locations, can render infection difficult to treat. Repeated or prolonged hospitalizations for previous surgical procedures may predispose to subsequent postoperative infection with multidrug-resistant bacteria. Attempts to reduce the incidence of infection have made the use of parenteral prophylactic perioperative antibiotic regimens for 2 to 5 days commonplace.

The development of meningitis is a concern with many craniofacial procedures; however, the dura provides a significant barrier to infection when painstaking neurosurgical technique is applied during repair. The presence of a cerebrospinal fluid leak is a predisposing factor, and

meningitis may be manifested years after the procedure in the case of a leak.[24] No cases of meningitis were identified from a combined report of complications after 567 procedures spanning 6.5 years at Medical City Dallas Hospital and at the Division of Plastic Surgery at the University of Pennsylvania in Philadelphia, primarily for cranial vault remodeling.[10] Similarly, meningitis was not identified from an earlier report of 170 transcranial operations spanning 10 years at the South Australian Cranio-Facial Unit in which 53 accidental dural tears occurred and 32 planned dural openings were performed.[8] Nonetheless, meningitis has been documented to occur in association with a frontal abscess with osteomyelitis, subgaleal fluid infection, contamination of cerebrospinal fluid drains, and monobloc advancement.[11,24]

As with many procedures, longer operative times result in more infections. Staging of surgeries for complicated problems has helped manage the risk for infection. The Australian group just mentioned documented an average operative time of 10.5 hours for patients in whom a postoperative infection developed, which was 2.5 hours longer than operations on patients in whom an infection did not develop.[8] Longer and more complicated monobloc advancement procedures have been associated with infection rates as high as 45 percent,[11] whereas anterior cranial vault remodeling may be associated with infection rates as low as 2.5 percent.[10] The dura encountered during primary craniofacial procedures is manipulated more easily and has better vascularization than does the scarred dura encountered in more complicated and laborious secondary procedures, which are associated with higher rates of infection.[9,10] Additionally, craniofacial postoperative infections develop in infants far less frequently than in adults.[8,10] Of the common procedures, infection remains a relatively rare complication of the less complicated Le Fort I maxillary osteotomy. In a large review of outcomes of 1000 such procedures, only 1.1 percent developed abscess or related infection.[13] Infections complicating distraction osteogenesis have been reported to occur in 9.5 percent of cases; however, osteomyelitis or deep infection requiring removal of instrumentation is less common, occurring in 0.5 to 0.9 percent of cases.[16]

As experience in craniofacial surgery has grown, the reduction in the frequency of infection has been attributed to shortened operative time, attempts to avoid entrance into the contaminated sinus cavities (an easier task in young children, in whom the sinuses often are still poorly developed), and mucosal repair at the end of surgery.[26] The mean time to diagnosis of infection is approximately 10 days.[11]

MICROBIOLOGY

Organisms causing infection include flora of the skin such as *Candida albicans*, *Staphylococcus aureus*, *Staphylococcus epidermidis*, beta-hemolytic streptococci, and *Propionibacterium acnes*. Resident flora of the oropharynx such as *Bacteroides* spp., *Corynebacterium* spp., various α-hemolytic streptococci, *Streptococcus pneumoniae*, *Morganella morganii*, *Eikenella corrodens*, *Haemophilus influenzae*, and *H. parainfluenzae* can be causative, as can *Pseudomonas aeruginosa*, *Escherichia coli*, *Klebsiella* spp., and *Acinetobacter calcoaceticus*.[6,10,28] Infections are often polymicrobial. Procedures that do not violate the mouth or paranasal sinuses are usually the result of skin flora. The frequency of infection with *Candida* spp. may rival the frequency of infection with more common bacteria.[10,27,28]

PREOPERATIVE PREPARATION, INTRAOPERATIVE IRRIGATION, AND PERIOPERATIVE ANTIBIOTIC THERAPY

Because wounds created during craniofacial surgery fall between the clean-contaminated category and the contaminated category,[6,7] screening for and treating dental caries, periodontal disease, and acute sinusitis is prudent before embarking on procedures involving intraoral incisions and trans-sinus osteotomies.[25] Vaccination of undervaccinated or unvaccinated children with pneumococcal vaccines during the planning process may be wise.[24] Some surgeons make use of intraoperative antibiotic-containing irrigants to help reduce the incidence of infection. These irrigants may be flushed over the intact cranium after subperiosteal exposure and again before skin closure. Other surgeons prefer to use a solution of one part povidone-iodine to four parts saline for intraoperative irrigation.[25] No strong evidence supports any one approach over another for reducing infection.[11]

Continuation of antibiotics beyond the intraoperative period is similar to the approach used in treatment of an open fracture and not very much like antibiotic prophylaxis in the traditional sense. The choice and duration of perioperative antibiotics vary among surgical centers and their surgical teams. Antibiotic regimens may include penicillin, ampicillin-sulbactam, a cephalosporin, clindamycin, or any two of these drugs in combination.[6,7,10,11,13] Erythromycin is used in penicillin-allergic patients in some centers.[1]

The optimal duration of perioperative antibiotic therapy is not clear. Higher infection rates occurred in some centers that tried restricting antibiotics to intraoperative use only.[1] Reports from one orthognathic surgical center showed a 10-fold reduction in infection rates with a 5-day antibiotic regimen in comparison with a single-day regimen.[2] Longer durations of treatment with postoperative antibiotics may be needed for patients with more heavily contaminated wounds, such as those found to have sinusitis.[6] Some advocates of a shorter duration of treatment with perioperative antibiotics suggested that longer administration of perioperative antibiotics contributes to infection with gram-negative organisms or may result in infection with more resistant gram-negative bacilli such as *P. aeruginosa* or other pathogens such as *C. albicans*.[7-11]

EVALUATION

Signs of postoperative craniofacial surgical infection include fever, warmth, tenderness, and erythema; and

rapid recurrence of swelling.[5] Yet, fever is a normal physiologic response to craniofacial surgery, occurring up to 5 days postoperatively.[9,21] Periorbital swelling may persist for some time and vary with sleeping position. Violaceous discoloration and bruising of the overlying skin are common. Distraction pins may dislodge as the integrity of the bone is compromised by infection.[23]

Purulent or seropurulent wound drainage may indicate underlying soft tissue and possibly bone infection. Wound drainage, pooling, and lack of wound healing at one location should prompt exploration for undiscovered infection elsewhere.[5] Laboratory abnormalities may be subtle. Leukocytosis may be present. The erythrocyte sedimentation rate has been shown to peak approximately 5 days after major orthopedic surgery and to decline slowly and irregularly for a period of 3 to 9 weeks, but it provides little diagnostic value initially.[3,14,22] C-reactive protein (CRP) levels peak within 2 to 3 days but usually normalize within 3 weeks.[3,14,19,22] Because an abrupt increase in CRP may be indicative of infection, some orthopedic centers monitor CRP levels to assist in early detection of infection after elective procedures such as total joint replacement and spinal surgery.[14,22] There may be value in following the CRP level in craniofacial patients postoperatively.

Needle aspiration of underlying fluid collections is the best primary means of diagnosing infection, especially if significant residual postoperative swelling has rendered clinical assessment of a particular area difficult. Diagnostic imaging such as computed tomography with contrast enhancement or magnetic resonance imaging may identify occult fluid collections, but diagnosing bone infection, especially in the flat bones of the cranium, is difficult with these modalities. Surgical exploration of suspected areas of infection remains the most helpful method to provide diagnostic information regarding infection.

TREATMENT

Management of infections complicating craniofacial procedures is primarily surgical. Open débridement, inspection and scraping of devitalized and contiguous bone, and copious pressurized saline irrigation may be curative. Removal of all hardware, while desirable, is often impractical. Successful treatment of these infections has been reported in some surgical centers in which the initial bony débridement was limited to areas of visibly apparent osteitis.[10] The value of adding antibiotics to the irrigant is questionable. Some physicians argue that irrigation with povidone-iodine may devitalize tissues that participate in the healing process and should not be used, whereas other physicians avoid using povidone-iodine irrigation because of concern about systemic iodine absorption.[10]

Placement of several drains prevents accumulation of sequestered focal soft tissue fluid collections. Resolution of drainage and subsequent wound healing can be a sign of cure. Continuous subgaleal flow-through irrigation with saline at a rate of 15 to 30 mL/hr (with or without antibiotic additives) is an adjunctive measure instituted by some surgeons.[10]

In infections acquired during cranioplasty, some patient groups may fare well with attempted preservation of a bone flap with minor surgical débridement and systemic antibiotic therapy. Within a small group of five patients who had undergone craniotomy without a history of previous craniotomy, radiation therapy, or skull base surgery, operative débridement accompanied by culture and susceptibility data–driven systemic antibiotic therapy was successful in treating infection with a mean of 35 ± 20 months of follow-up. Several other patients required second-look operations with more débridement, but they did not require removal of the bone flap and were cured. In the same study, the two other subjects had undergone more extensive craniofacial surgery and had recurrent infection requiring removal of the bone flap at 2 months after presentation in one patient and at 29 months in the other one, respectively; this finding bears out the concern that contamination of the bone flap can result in persistent, long-standing infection.[4]

For infections that complicate procedures not involving the oropharynx or sinus cavities, an antistaphylococcal antibiotic such as vancomycin, cefazolin, nafcillin, or clindamycin may be an appropriate empirical antibiotic choice pending the results of intraoperative drainage and débridement cultures. A third-generation cephalosporin with or without an aminoglycoside may be considered if the risk for developing an infection with a nosocomial pathogen is high because of prolonged hospitalization or persistent tracheal colonization with gram-negative bacilli such as *Pseudomonas*[8] or if infection of the central nervous system threatens. Infections complicating procedures involving the oropharynx or sinuses often are caused by organisms resistant to the perioperative antibiotic chosen.[6] Thus, it may be reasonable to consider antibiotic therapy with clindamycin or metronidazole when a cephalosporin has been used or treatment with a second- or third-generation cephalosporin or ampicillin-sulbactam when clindamycin has been used prophylactically. The duration of antibiotic therapy must be individualized to each case. A period of 6 weeks of antibiotic therapy has been suggested for patients with suspected osteomyelitis.[21] Some would reserve oral antibiotic suppression for patients who live long distances from the craniofacial surgery center who cannot be observed closely.

CHAPTER 76

Infections in Burn Patients

Janak A. Patel • Natalie Williams-Bouyer

According to the American Burn Association, approximately 450,000 persons were treated for burns in 2011 in the United States; of these, approximately 45,000 were hospitalized and approximately 3,500 died of the burn injury.[4] About 75 percent of the deaths occurred before arrival at the hospital. For those who are hospitalized, mortality peaks 20 days after hospital admission.[75] Improvement in the rate of burn-associated mortality is a direct result of advancement in burn care, comprising developments in fluid resuscitation, wound care, early excision and grafting, nutritional support, infection control, and antimicrobial therapy. The mortality rates and lengths of stay of children with burn injury have been reduced greatly in the past several decades. In the 1960s, the likelihood of survival was only 50 percent for pediatric patients with burns covering 35 to 44 percent of the total body surface area (TBSA), and few children with burns covering more than 45 percent of TBSA survived. The average length of stay was 103 days. In 2011, the LA_{50} (lethal burn size for 50% of patients) for children younger than age 16 years exceeded 90 percent of TBSA.[4] The overall mortality rate for children is less than 1 percent, which is much lower than that of adults, who have mortality rates in the range of 2 to 26 percent.[4] In a recent autopsy study at the Shriners Hospitals for Children–Galveston, sepsis was found to be the leading cause of death and accounted for 47 percent of deaths.[139]

BURN WOUND

Burn Wound Depth

Burn wounds are categorized by their depth (Fig. 76-1).[48] Accurate assessment of the depth of burn wounds is important in planning the early definitive care of an individual patient. However, the majority of burn wounds are evaluated by clinical examination only. In this respect, laser Doppler imaging is an important advance in noninvasive techniques for predicting burn wound depth.[72]

First-degree burns consist of epidermal damage only. These wounds are painful and erythematous as a result of local vasodilation. They heal spontaneously, usually without forming scars, within 7 days.

Second-degree burns are partial-thickness injuries and are further categorized as superficial or deep. The epidermis and superficial portions of the dermis are injured in superficial second-degree burns. These wounds are painful and often result in formation of blisters. Healing occurs through epithelial migration from the wound edges, hair follicles, and sebaceous glands. Relatively little scarring occurs, and reepithelialization occurs within 2 weeks. Deep second-degree burns are much more serious. The majority of the dermis is destroyed, leaving the bases of the epidermal appendages spared. The nerve endings also are destroyed, rendering the wound insensate. Blisters usually are not present, owing to the thicker formation of eschar. These wounds are treated as full-thickness injuries. Reepithelialization is tenuous and slow. The protracted inflammatory phase often results in excessive deposition of collagen and extensive scarring.

Third-degree burns are full-thickness injuries to the skin. Healing occurs by contraction and reepithelialization from the edges of the wound. As with deep second-degree burns, these wounds are insensate and without blistering. Infants and young children have a much thinner dermal layer to their skin, resulting in increased propensity for deeper burn injury. Treatment of third-degree burns is excision and skin grafting.

Fourth-degree burns extend into the deep tissue, which includes muscle, bone, and viscera. Treatment is débridement and possible amputation. Closure of these wounds may vary from primary closure after amputation to skin grafting and possibly flap reconstruction.

Cytologic Findings

The effects of extreme heat on the skin lead to cellular and subcellular impairment. The determining factors of how severe a burn will be are the temperature, the length of exposure, and the actual burning agent. Moritz and Henrique showed that the skin is able to withstand temperatures up to 40° C (104° F) for relatively long periods of time before an injury becomes apparent.[95] Increase in temperature leads to cell membrane dysfunction as ion channels are disrupted, resulting in sodium and water intake. As temperatures exceed 45° C (113 °F), protein denaturation supersedes the cell's reparative capabilities and oxygen radicals are liberated. Plasma membrane necrosis has been observed in cells exposed to 45° C for 1 hour. Other cytologic findings in thermal injury include the redistribution of solid and fluid components of the cell nuclei. Imbibition of fluid results in nuclear swelling, rupture of membranes, and pyknosis. As denaturation proceeds, vital cellular metabolic processes are injured. If enzyme activity is decreased to less than 50 percent of its normal level, cell death occurs. In lesser degrees of enzyme impairment, cell recovery may be possible.

Local Tissue Changes

Local burn injury is classically described by Jackson in three concentric zones. As temperature increases, protein denaturation results in coagulation.[61] The protein architecture is destroyed and new aberrant macromolecules are formed. The central area of a burn wound is that which is in direct contact with the source of heat. Cell necrosis is complete and is called the *zone of coagulation*. Cellular recovery is impossible, and the severity of injury decreases from the surface to the deeper levels. This zone is called the *burn eschar*. At the peripheral margins of the zone of coagulation, a less injured zone is present. The cells in this *zone of stasis* show direct injury from the heat, but the damage is not lethal. However, blood flow becomes progressively impaired to this area. Ischemia to the already compromised cells may lead to necrosis and conversion to dead eschar. Circulatory impairment occurs via adherence of neutrophils to the vessel wall, deposition of fibrin, formation of platelet microthrombus, vasoconstriction, and endothelial swelling. Heat-compromised erythrocytes lose their ability to deform, and their passage through microvessels is impeded. The circulatory embarrassment may be delayed for up to 24 hours, and the ischemia may progress for up to 48 hours after the burn has occurred. If stasis conditions are minimal, the injury may be halted and cell recovery may occur within 1 week. However, this tissue is fragile and further insults such as infection, hypovolemia, pressure, and overresuscitation can lead to further necrosis. Finally, the *zone of hyperemia* lies peripheral to the zone of stasis. This zone sustains minimal injury and often recovers within 7 to 10 days. Notable vasodilation is caused by potent vasoactive mediators secondary to the inflammatory response. Complete recovery is expected in this zone, barring further trauma or infection.

Burn Inflammation

Many of the just mentioned processes are either part of or result from the inflammatory process. Cellular infiltration, initiated by local inflammatory mediators such as prostanoids and leukotrienes, as well as proinflammatory cytokines from the burn wound, begins with the arrival of neutrophils at 4 to 5 days post burn, followed by macrophages.[121] The neutrophils further mediate damage by releasing oxygen free radicals.[42] Reestablishment of blood flow in the zone of stasis is yet another setting in which oxygen free radicals are produced, leading to further injury. This phenomenon of ischemia-reperfusion injury occurs as oxygen is restored to the tissues.[66] Inflammation becomes prominent at 7 to 10 days. Consequently, blood flow is maximal at this stage, creating a troublesome and hazardous setting for surgical excision of the eschar. Along with local inflammatory responses, several systemic responses occur with burns of more than 15 percent of the TBSA.

Inhalation Injury

Burn victims, especially those trapped in enclosed areas, injure the respiratory tract on inhalation of toxic gases from surrounding burning materials. An actual thermal airway injury is quite rare. The upper airway is rather effective in cooling and warming inspired air. Also, air has a very low heat capacity. To cause a direct injury to the airway, the flames must come into direct contact with them. Injury to the oropharynx after inhalation of toxic gases resembles thermal injury elsewhere in the body.[1] Protein denaturation, release of inflammatory mediators, and increased cellular and microvascular permeability all occur, leading to airway edema and consequent obstruction of the airway.

The chemical injury from inhalation of toxic gases can damage the tracheobronchial tree. First, separation of ciliated epithelial cells from the basement membrane occurs.[12] Next, the circulation of blood to the lung, as well as to the bronchial tree, is increased owing to vasodilation. Shortly thereafter, edema is evident. The inflammatory phase is followed by an exudative phase.[58] Furthermore, the protein component of this fluid is composed of lung lymph and induces bronchoconstriction. As postburn time increases, fibrin casts are formed from the exudates, resulting in obstruction of the airway. As the epithelium sloughs and formation of fibrin casts increases, susceptibility to infection also increases. Pneumonia leading to sepsis and death are well-known sequelae at this stage. Finally, formation of pseudomembranes proceeds and then squamous metaplasia follows.[106] Healing may take weeks to initiate, and permanent damage to the airway (e.g., stenosis and formation of tracheal granulomas) may occur.

INFLAMMATORY AND IMMUNE RESPONSES IN BURNS

Intact human skin is vital for preservation of the host's protection against infection. A combination of impaired local and systemic host defenses and loss of the skin barrier are major factors responsible for the increased susceptibility to infections in patients with burns. The major elements initially contributing to the inflammatory response that occurs after burns are incurred include the plasma proteins, mast cells, tissue macrophages, and systemically recruited neutrophils and monocytes.

Alterations in the host defenses include induction of local and systemic cytokine synthesis, decreased immunoglobulin levels, changes in the concentration and activity of both the classical and alternative complement pathways, reduced levels of circulating plasma fibronectin, depressed serum opsonic activity, and impairment of the macrophages, lymphocytes, neutrophils, and the reticuloendothelial system. However, many mechanisms of immune alterations remain unknown; for example, an association of the volume of blood transfusions with increased mortality rates and infectious episodes in patients with major burns was observed in two reports.[63,106] The immunologic status of the burn patient has a measurable impact on survival, death, and major morbidity.

The Cytokine Response

After burn injury occurs, numerous cytokines are induced rapidly. Many cytokines correlate with the severity of the burn injury and the prognosis. Recent studies at Shriners Hospitals for Children–Galveston have shown a specific pattern of systemic cytokine responses in children with thermal injury. Compared with unburned healthy children, children with burns covering more than 40 percent of TBSA had significant increases in serum levels of 15 cytokines and immunoregulatory molecules during the first week after incurring the thermal injury: interleukin (IL)-1β, IL-2, IL-4, IL-5, IL-6, IL-7, IL-8, IL-10, IL-12p70, IL-13, IL-17, interferon gamma (IFN-γ), monocyte chemoattractant protein-1 (MCP-1), macrophage inflammatory protein (MIP)-1α, and granulocyte colony-stimulating factor (G-CSF).[37,75] The amount of granulocyte-macrophage colony-stimulating factor (GM-CSF) was significantly increased during the second week after burn occurred. Within 5 weeks, the serum concentrations of most cytokines decreased, approaching normal levels. In another study of children, serum IL-6, IL-8, IL-10, IL-12p70, IL-13, IFN-γ, tumor necrosis factor-α, MIP-1β, MCP-1, G-CSF, and GM-CSF values were significantly increased in large burns.[36,75] In general, there is a clear increase in these cytokines when the affected TBSA is greater than 60 percent when compared with burns affecting a lesser TBSA.[75]

In children with inhalation injury, the serum cytokine studies at enrollment showed significant reduction in level of IL-7 and elevation of IL-12p70, as compared with children without inhalation injury.[36] However, 5 to 7 days later, the levels were comparable. Host genetic factors also may affect the cytokine response in patients with burns. For example, single nucleotide polymorphisms for TNF-α (–308G), Toll-like receptor 4 (+896G), IL-6 (–174C), and CD14 (–159C) were significantly associated with an increased risk for severe sepsis after burns.[8] In another study, children with IL-10 (–1082GG) genotype, which is associated with high production of IL-10, were found to have an increased risk for sepsis.[107]

Complex cytokine pathways lead to several effects throughout the body. Among these, TNF-α may be the most important cytokine during acute inflammatory injury of burns because it induces production of C-reactive protein and IL-6, migration of and phagocytosis by neutrophils and macrophages, hormone regulatory processes, particularly hypothalamic thermoregulation, and insulin hypersensitivity.

Neutrophils

Thermal injury induces neutropenia and myeloid maturation arrest despite elevated G-CSF levels.[123] The degree of neutropenia correlates with the reduction in bone marrow G-CSF receptor expression. The neutrophils of patients with burns also are functionally altered[96]: The expression of the Fc receptor is decreased, and intracellular killing capacity is depressed (this is a differential suppression, more for some organisms than others) and is accompanied by a brief increase in neutrophil respiratory burst response. Failure of initial alkalization of the phagolysosome and alteration of subsequent kinetics of acidification also occur.[16] This depression of oxygen-independent bactericidal mechanism may impair the capacity of the neutrophil for intracellular killing after a thermal injury occurs. Expression of CD16 (Fc receptor [FcR], Fc immunoglobulin G [IgG] receptor) and CD11 (adhesion molecule) on neutrophils is impaired after a major injury occurs; this reduction appears to be related directly to the appearance of bacteremia or pneumonia.[6] These changes in expression of adhesion molecules, which is closely related to chemotaxis, may play a part in the failure of delivery of neutrophils in adequate numbers to the local site of a burn. Furthermore, a defect is present in actin polymerization in the neutrophils of patients with burns; as a basic mechanism of chemotaxis, it also may contribute to a failure of motility.[132]

Generation of leukotrienes from the neutrophils of severely burned patients also is impaired and appears to be based on the availability, or lack of availability, of the metabolizable substrate-free arachidonic acid.[71] Because leukotriene B also is a potent neutrophil chemotactic agent, this impairment may further contribute to the failure of neutrophil function.

Complements

The fluid of the burn blister shows much lower opsonic activity for bacteria such as *Pseudomonas aeruginosa* than the patient's own serum.[102] A mild impairment of production of C3 and release by macrophages of burn patients in vitro also occurs. Systemically, both the classical and the alternative pathways are depleted, but the alternative pathway is more profoundly perturbed. After

the development of bacteremia, additional complement activation and depletion occur.[130]

Macrophages

Suppression of the ability of the reticuloendothelial system to take up particulate material was among the original observations of burn immunology made in the 1960s. More recent reports, however, have described the demonstration of a differentially increased uptake of colloid in alveolar macrophages compared with other organs, perhaps indicating alveolar macrophage activation. Macrophages and monocytes appear to be activated in a fashion similar to that of lymphocytes after thermal injury occurs. Activation of macrophages, as measured by the serum neopterin level, is increased after thermal injury occurs.[7] This activation is confirmed by increased expression of the monocyte cell surface antigens C3b and iC3b.[94] At the same time, expression of human leukocyte antigen (HLA)-DR, HLA-DQ, and HLA-DP by monocytes is reduced, and these class II antigens are obligatory for many cell-mediated immunologic processes, thereby implying that a possible loss of function of monocytes occurs after thermal injury.[45] Production of C3 by macrophages is suppressed in patients with burns, but the synthetic ability for key cytokines such as IL-6 is increased.[143]

Peripheral blood monocytes are superstimulated to produce large amounts of IL-1, leading to exhaustion of the function on monocytes.[83] Reduced production of IL-1 by monocytes was found in patients with complicated organ injury, multiorgan failure, and systemic infection. Blood monocytes of patients with burns produce significantly more IL-10 at 7 to 10 days after burn injury, which correlates significantly with subsequent septic events.[68]

T Lymphocytes and Cell-Mediated Immunity

Early studies of T cells in patients with burns showed a variety of changes: impairment in mitogenic and antigenic responsiveness of lymphocytes, suppression of graft-versus-host reactivity related to the size of the burn, suppression of delayed cutaneous sensitivity tests, and diminution in both numbers of peripheral lymphocytes and concentration of thoracic duct lymphocytes. Whether the failure of T cell functions is due to an intracellular defect related to thermal injury, the result of "overuse," or indirectly the result of downregulation by the cytokine cascade or other products of the inflammatory reaction remains controversial. A study has shown that severe burn injury could result in activation and maturation of regulatory T cells leading to immunosuppression.[60] The elevation of levels of cytokines produced by regulatory T cells and the activation markers on the surface of these cells correlate with burn size and are higher in those with sepsis than those without. However, among septic patients, the regulatory T cell parameters in the survival group were markedly lower than those with fatal outcome, suggesting that persistence of a pronounced immunoparalysis induced by regulatory T cells after severe sepsis is associated with poor outcome after burns.

Analysis of peripheral blood T cells supports the theory that, rather than an absolute reduction in CD4 and an increase in CD8 cells, a redistribution of lymphocyte traffic may occur.[104] Suppression in the numbers of the total population of lymphocytes is the only consistent overall change. Furthermore, not only does lymphocyte traffic between stores of central lymphocytes and the peripheral blood occur after a thermal injury, but the responsiveness of these populations of lymphocytes also varies according to the site; for example, splenic lymphocytes of experimentally burned animals remain most profoundly depressed in response to antigenic stimulation, compared with the peripheral blood and other organs.[29] In addition, in peripheral blood, the appearance of "activation" antigens on CD4 and CD8 cells (HLA-DR, IL-2 receptor [IL-2R], and transferrin receptor) is depressed significantly as early as 1 day after burn injury occurs.[87]

Addition of recombinant IL-2 does not appear to reverse the suppression of the appearance of surface markers such as IL-2R in burn patients, although it does not improve the response of natural killer (NK) cells to stimulation.[40] In experimental preparations, at least some of the observed T-cell suppression can be alleviated by early removal of the burn wound, thereby creating one further argument for promptly closing the burn wound.[51]

B Lymphocytes and Humoral Immunity

The function of B cells after the occurrence of a thermal injury is less well documented than is that of macrophages or T cells. The expression of this major histocompatibility complex is impaired and, therefore, some diminution of B-cell function can be expected as a result of diminished recognition of antigenic presentation.[100] Under the influence of stress-induced corticosteroids, the number of circulating B cells is relatively increased compared with T cells in peripheral blood.[65] Spontaneous cytokine (IL-4 and IL-2)-induced expression of the activation antigen CD23 is reduced significantly during the second to fifth week after burn injury occurs.[118]

If the products of B-cell activation, namely, the immunoglobulins, are measured in vivo, the results are somewhat difficult to interpret because of the increased catabolism of protein and the leakage through the burn wound. Briefly, marked diminution of serum IgG concentration (total and all subclasses) is present; these levels return to normal between 10 and 14 days after the burn injury has occurred. Extremely low levels of IgG on admission (300 to 400 mg/dL) are predictors of a poor prognosis. Levels of IgM and IgA appear to be relatively unaffected. Overall, the defective production of immunoglobulin after a thermal injury occurs appears to be a factor of macrophage/lymphocyte interaction rather than a failure of intrinsic activity by B cells.[35]

BURN WOUND MICROBIOLOGY

A working knowledge of the common flora of burn wounds is essential to appropriately tailor therapy.

TABLE 76-1 **Tissue Association of Microorganisms Most Commonly Found in Burn Wound Infection**

Organism	Soft Tissue Skin	Upper Respiratory Tract	Lower Respiratory Tract	Endocardial	Gastrointestinal	Urogenital	Bone and Joint

NF, normal flora; *P,* pathogens; (–), normally not found, but these organisms should not be ignored when encountered.
Modified from Heggers J. Microbiology for surgeons. In: Kerstein MD, editor. *Management of surgical infections.* Mt. Kisco, NY: Futura Publishing, 1980. p. 27-55.

Pathogens peculiar to thermal injuries are basically no different from the normal flora of the environment. Table 76-1 shows the types of microorganisms found in various body tissues and secretions as either normal flora or as pathogens. However, the organisms causing infections change over the course of burn wound treatment. Gram-positive organisms prevail in the early postburn period and then are replaced by gram-negative bacteria and fungi.[33] Many of these organisms produce biofilms in burn wounds. The biofilms consist of organisms surrounded by a matrix consisting of various proteins, polymers, complex carbohydrates, and water. Biofilms are associated with development of antibiotic resistance because antibiotics do not penetrate through the matrix in sufficient concentration. Biofilm formation also inhibits effective local immune response as well as wound healing. Using electron microscopy, Kennedy and colleagues showed that in both ulcerated and escharotomy sites, evidence of biofilm was seen as early as 7 days post injury.[69] Formation of biofilm is best prevented by early excision and coverage of the wound with topical antimicrobial agents.

The organisms that predominate as causative agents of burn wound infection in any burn treatment facility change over time. For example, at Shriners Hospitals for Children–Galveston, from 1989 to 1999, only 42 percent of children died of sepsis due to multidrug-resistant organisms and in 25 percent of these children *Pseudomonas* was the responsible organism. From 1999 to 2009, 86 percent of patients died of sepsis due to multidrug-resistant organisms and in 64 percent of these children again the cause was *Pseudomonas* infection. In this latter period, *Acinetobacter* also emerged as a major pathogen of death due to sepsis while the role of *Klebsiella* declined.

Gram-Positive Bacteria

The gram-positive predominance is consistent with the normal inhabitants of the skin before the thermal injury. *Staphylococcus* spp., *Micrococcus* spp., *Streptococcus* spp., *Pediococcus* spp., and *Enterococcus* spp. are gram-positive cocci commonly encountered in burn wounds. Erol and colleagues demonstrated that coagulase-negative *Staphylococcus* and *Staphylococcus aureus* were the most prevalent isolates in admission cultures, followed by diphtheroids.[33] These organisms can be life threatening as invasive infections or simply be locally colonized. The distribution of gram-positive bacteria at Shriners Hospitals for Children–Galveston, which receives pediatric burn patients from all over the world, is shown in Table 76-2. For the year 2011, the gram-positive cocci accounted for 55 percent of bacterial isolates. Within this group, staphylococci are more prevalent (52%) than enterococci (22%). Among *S. aureus* isolates, the rates of methicillin-resistant (MRSA) and methicillin-sensitive (MSSA) isolates were equal (about 10%). Interestingly, the rate of MRSA in the burn patient population is lower than the community rate of MRSA, which is about 60 percent of *S. aureus* isolates in the region around our facility.

Because of such resistance patterns, Cook stresses the importance of microbial surveillance and epidemiologic studies.[24] This approach is thought to reduce the prevalence of MRSA, yet it may be inadequate for eradicating or preventing outbreaks. Minimizing transmission and infection is emphasized. However, Reardon and associates suggest that this process is time consuming and requires extensive resources for little gain.[110] Colonization with MSSA and MRSA in 86 patients was studied and found to have no significant changes on length of

TABLE 76-2 **Bacteria Isolated from 168 Inpatient Acute Care Pediatric Burn Patients Admitted to Shriners Hospitals for Children–Galveston (January 2011 to December 2011)**

	No. (%) of Isolates
Gram-Positive Organisms	
Methicillin-resistant *Staphylococcus epidermidis*	86 (19.4)

ESBL, extended spectrum β-lactamase.

stay, number of operations, or mortality between these two organisms. However, the presence of either type of *S. aureus* significantly increased the number of surgical procedures performed and the lengths of stay. Many burn units report frequent colonization of burn patients with toxic shock toxin (TSS-1)–producing strains of staphylococci; however, their presence does not correlate well with increased morbidity or mortality rates.[23]

In the past, group A β-hemolytic streptococcus frequently was the cause of epidemics in burn units, but it seldom is encountered today because of the frequent empirical use of antibiotics for manipulations of burn wounds. Other β-hemolytic streptococci belonging to groups B, C, E, F, and G can be encountered as well.[81] Significant infection-control vigilance still is necessary, because occasional clusters of outbreaks of group A streptococcal infection continue to be reported.[48,113] Fortunately, group A streptococcus remains uniformly sensitive to penicillins; hence, prophylaxis and treatment are easily accomplished.

Although enterococcal infections (*Enterococcus faecalis* and *Enterococcus faecium*) account for only 22 percent of burn-wound infections caused by gram-positive bacteria (see Table 76-2), a significant cause for concern is the emergence of vancomycin-resistant *Enterococcus* (VRE) in burn units.[77,79] Although additional morbidity associated with VRE itself is not clear, when it occurs as a polymicrobial bacteremia, a mortality rate as high as 20 percent has been noted.[79]

Other gram-positive bacilli include the aerobic *Corynebacterium* spp. and *Listeria* spp., as well as the spore-forming *Bacillus* spp. (aerobe) and *Clostridium* spp. (anaerobe). *Bacillus* spp. and *Clostridium* spp. are associated with burn wounds that have come in contact with contaminated soil. In avascular muscle injuries (e.g., electrical injuries or crush injuries combined with burns), the risk for developing tetanus (from infection with *Clostridium tetani*) is high and has led to the practice of using tetanus immunoprophylaxis and booster vaccines.[78,120]

Gram-Negative Bacteria

The presence of the gram-negative bacteria in burn wounds is due in part to translocation of the bacteria from the gastrointestinal tract of the patients.[9] In a study of children with burns at Shriners Hospitals for Children–Galveston, patients with large wounds (>50% TBSA) were found to have significantly higher colonization with their fecal gram-negative bacteria than were those with smaller wounds.[38] *P. aeruginosa* bacteremia is predicted by isolation of *P. aeruginosa* from another site (wound, urine, or sputum), and the prior nonblood isolates of *P. aeruginosa* can correctly predict the antimicrobial sensitivity pattern in 75 percent of patients.[86] At Shriners Hospitals for Children–Galveston, gram-negative bacteria account for 45 percent of the total bacterial isolates of the wound (see Table 76-2), and most of these bacteria produce extended spectrum β-lactamase (ESBL) enzyme. *Escherichia coli* and *Klebsiella pneumoniae* are the predominant ESBL-producing bacteria. Bennett and coworkers have shown that infections caused by ESBL-producing *K. pneumoniae* are predictive of death when occurring in older persons.[15]

Although the carbohydrate-fermenting Enterobacteriaceae account for 64 percent of the gram-negative isolates as a whole, *P. aeruginosa* and other nonfermenters are also important in burn patients. Other important gram-negative bacteria include the Enterobacteriaceae such as *E. coli*, *Enterobacter cloacae*, *K. pneumoniae*, and *Serratia marcescens*. Enterobacteriaceae also are encountered as a cause of nosocomial pneumonia in patients with inhalation injury who are on ventilators, and they are a

cause of urinary tract infection in patients with indwelling urinary catheters. *Acinetobacter*, an increasingly more common cause of gram-negative infections, has been found more frequently in burn patients with glucose intolerance or preexisting diabetes mellitus[39] and in patients with more severe burns and comorbidities.[3]

Even without invasive infections, gram-negative bacteria have been implicated in systemic inflammatory diseases, including shock and disseminated intravascular coagulation, secondary to the circulation of bacterial endotoxin from the gut and the burn wound.[74,84] Often gut decontamination is instituted to reduce the incidence of endotoxin-mediated disease.

Fungi

Until the advent of topical antimicrobial agents and systemic antibiotics, fungal infections were not common developments in patients with burns. The burn wound is the site most commonly infected, although fungemia and dissemination to the respiratory tract in patients on ventilators and to the urinary tract in patients with indwelling catheters are encountered frequently. *Candida* spp. are the most common fungal colonizers of the wound (Table 76-3); however, less than 20 percent of patients develop widespread candidiasis. Overall, the rate of candidemia in the burn patient population is 3 to 5 percent, and burn wound invasion has a comparable rate. A study of children with burn injury at Shriners Hospitals for Children–Galveston showed that those developing candidemia did so during the first week post burn and 7 days after excision of burn eschar.[28] One hypothesis is that massive burns with immunosuppression are further suppressed by repeated surgical intervention, anesthesia, and perioperative use of broad-spectrum antibiotics, further predisposing these patients to early development of *Candida* septicemia. In one study, the attributable mortality with candidemia was 15 percent.[93] With early recognition of invasion of burn wounds by routine biopsies, wound swabs, and early amphotericin therapy, the mortality rate has been reduced to less than 10 percent, as compared with 60 to 90 percent reported in earlier series.[119]

Unlike *Candida*, true fungal infections caused by *Aspergillus*, *Penicillium*, *Rhizopus*, *Mucor*, *Rhizomucor*, *Fusarium*, and *Curvularia* occur early in the hospital course, specifically in those exposed to the spores on the ground or in water at the time the injury occurred. Once colonized, broad nonbranching hyphae extend into subcutaneous tissue and stimulate an inflammatory response. Vascular invasion occurs frequently and often is accompanied by thrombosis and avascular necrosis, which is clinically observed as rapidly advancing dark discolorations of the wound margin. Systemic dissemination occurs with invasion of the vasculature.

TABLE 76-3 Medically Important Fungi Isolated from Acute Care Pediatric Burn Patients Admitted to Shriners Hospitals for Children–Galveston (January 2011 to December 2011)

Organism	No. (%) of Isolates

*Includes *C. albicans/dubliniensis* (n = 39); *C. glabrata* (n = 11); *C. parapsilosis* (n = 9); *C. tropicalis* (n = 5); *C. rugosa* (n = 3); *C. zeylaroides* (n = 1); *C. stellatoidea* (n = 3); *C. krusei* (n = 3); and *C. paratropicalis* (n = 1).

Viruses

Linnemann and MacMillan performed a retrospective survey of serum for viral antibodies in pediatric burn patients; 22 percent had fourfold increases in antibodies to cytomegalovirus (CMV), 8 percent had increases to herpes simplex virus (HSV) and to Epstein-Barr virus, and 5 percent had increases in antibodies to varicella-zoster virus (VZV).[82] None of the patients had evidence of adenovirus or hepatitis B virus infection. On the basis of these observations, a prospective study of viral infections, using both serologic and viral culture techniques, was performed. This study showed that CMV infection developed in 33 percent of the children, HSV infection occurred in 25 percent, and adenovirus infection was noted in 17 percent. CMV infections developed in all of the most severely burned children, and both primary and reactivation infections were observed. Most primary CMV infections that develop during treatment for burns are likely to occur from transfusion of blood products. CMV infection typically occurs approximately 1 month after the burn occurs and clinically presents as fever of unknown origin with lymphocytosis; however, it rarely alters the patient's clinical course.[27] Kealey and colleagues[67] have shown that 56 percent of burn patients who initially were seropositive for CMV had a fourfold or greater rise in CMV antibodies as evidence of CMV reactivation. These patients tended to be younger, to have a larger burn area, and to have a longer hospital stay. No patient who experienced CMV infection, whether primary or reactivated, had serious complications attributable to CMV. On the basis of these observations, despite the availability of anti-CMV agents such as ganciclovir and valganciclovir, treatment of CMV infection remains controversial.[111]

Since the screening of blood began, hepatitis C virus (HCV) has been an important risk factor. Coursaget and colleagues screened 45 burn patients for anti-HCV antibodies at the time of burn injury and more than 6 months post burn.[25] HCV infection was detected in 18 percent of these patients as a consequence of the numerous transfusions of blood or blood derivatives used during the postburn treatment. Five patients displayed evidence of anti-C100, anti-C33c, and anti-core antibodies together; two patients had only anti-C100 and anti-C33c antibodies, and the last one showed only anti-core antibodies.

Chronic hepatitis was observed in 83 percent of HCV infections. Kinetics of appearance of anti-HCV antibodies varied among patients. Anti-core antibodies generally are the first to be detected at high levels; however, in at least one case, they were detected only 2.5 months after C100 and C33c antibodies were detected. The incidence of HCV using polymerase chain reaction (PCR) assay to detect the viral genome has not been evaluated in burn patients. Nonetheless, the current procedures used at blood banks have decreased the transmission of HCV by blood products.

Another transfusion-related agent is human immunodeficiency virus (HIV), which has become extremely rare as a result of the screening of donors that began in 1987 in the United States. However, significant risk existed prior to that period. A retrospective review of children with burn injury at Shriners Hospital for Children–Galveston who had received blood or blood products between 1978 and 1985 identified 52 patients at risk for developing HIV infection.[115] More than 50 percent of the identified population had received three or more units of blood or blood products during their acute hospital stay. A total of 214 patients (36.8%) were tested for HIV seroconversions: 5 tested HIV-positive by enzyme-linked immunosorbent assay (ELISA) and 4 were confirmed by Western blot, yielding a 1.9 percent incidence. The 4 confirmed patients received two to nine total-body blood volume turnovers during their postburn period in the hospital. HIV may affect the outcome of burn wound injury. A study of Malawian children showed that with burns affecting 11 to 30 percent of the body surface area, HIV-positive children had a mortality rate approximately twice that of HIV-negative children.[62]

HSV is of significant concern in burn units because it is a dermatopathologic virus. A review of the literature suggests that patients younger than 10 years of age were at greater risk for acquiring an HSV infection when the size of the burn wound was greater than 15 percent of TBSA.[52] However, the role of HSV in the healing of wounds is unclear. Bourdarias and associates showed that in 11 patients with burns, local areas of active epidermal regeneration were affected most often.[17] Acyclovir therapy was not used, and the duration of hospitalization was normal when compared with that for other children. Nonetheless, HSV in lungs may worsen morbidity. Byers and coworkers showed that the relative risk for developing HSV infection was higher for patients with adult respiratory distress syndrome but not for those with pneumonia.[20] Disseminated HSV infection also can be fatal.[20]

Another dermatopathologic virus is VZV. Miniepidemics of VZV have occurred within pediatric burn units.[138] With the routine VZV vaccination of young children (at 1 year of age) in the United States, the outbreaks of varicella in burn units are now uncommon. The characteristic fluid-filled lesions appear in partial-thickness burns that are healed or healing, as well as in uninjured epithelium and mucous membranes. The vesicles are much more destructive in the injured than uninjured skin and may present as hemorrhagic, oozing pock marks that are prone to development of secondary infection and subsequent scarring. Neovascularized skin grafts may be lost; therefore, further grafting procedures should be delayed until the lesions are quiescent.

The morbidity due to respiratory virus infections, particularly in those with inhalation injury, has not been studied well. We tested more than 100 pediatric burn patients for respiratory syncytial virus (RSV) during the winter seasons of 1995 and 1996. Only 6 patients were found to be positive for RSV, with one death (1% mortality rate).

Parasites

Parasitic infestation also is seen especially in children from the developing world. Because we see many patients who originate from Mexico, where such infestation is endemic, parasitemia has been found to complicate burn injuries. Parasites that are asymptomatic in sites such as the intestinal tract and the respiratory tract can become symptomatic as a result of the stress of a burn injury. At the Shriners Hospital for Children–Galveston, we have described three cases of *Ascaris* pneumonitis that exacerbated the smoke-induced lung injury.[53] In 2006, the parasites isolated most frequently were *Giardia lamblia* and *Blastocystis hominis*.

CLINICAL MANIFESTATIONS

Local Signs

An open burn wound is a favorable target for bacterial colonization. The progression from simple eschar colonization to the invasive process is favored by a series of factors related to the patient, such as extension and depth of the burn, age, presence of previous disease, and local conditions of the wound; to the microorganism, such as density, motility, toxins, and antimicrobial resistance; to iatrogenic causes such as prosthetic devices; and to the nosocomial spread of bacteria. It is essential to recognize the early signs of infection of a local burn wound by examining the wound at least once a day.

The local signs of burn wound infection include black or dark brown focal areas of discoloration, conversion of partial-thickness injury to full-thickness necrosis, hemorrhagic discoloration of subcutaneous tissue, enhanced sloughing of burned tissue or eschar, and purplish discoloration or edema of skin around the margins of the wound. Presence of *Pseudomonas* infection can lead to ecthyma gangrenosa and green pigmentation of subcutaneous fat. In fungal infection, centrifugal advance of subcutaneous edema with central ischemic necrosis and hemorrhagic saponification of subcutaneous fat in fungal infection can be seen. In viral infection, vesicular lesions in healing or healed partial-thickness burns and crusted serrated margins of partial-thickness burns may be observed.

Systemic Signs

Progression from local to systemic invasion can occur rapidly, which correlates with the size of the burn wound, the extent of environmental contamination, and the

TABLE 76-4 **Signs and Symptoms of Progression from Local Invasion to Systemic Illness**

Gram-Negative Sepsis	Gram-Positive Sepsis
Burn wound biopsy >10^5 organisms/g tissue and/or histologic tissue invasion	Same
Rapid onset, well to ill in 8-12 hr	Gradual
Temp. 37-39°C (98.6-102.2°F), can be normal, followed by hypothermia (34-35°C [93.2-95°F]), plus decrease in WBC	Temp. >40°C
WBC may be elevated	WBC 20-50 × 10^3, hematocrit decrease
Ileus	Same
Decreased blood pressure and urinary output	Same
Wounds develop focal gangrene, satellite lesions away from burn wound	Macerated wounds, ropy and tenacious exudate
Mental obtundation	Anorexic and irrational

Note: Five or more signs or symptoms are definitive diagnostic parameters.
WBC, white blood cell count.

surgical procedures. Early recognition of systemic invasion is critical to avoid the high rates of mortality. Many of the signs of sepsis resemble complications of the burn itself; for example, fevers, tachycardia, shock, and elevated or depressed neutrophil count can occur in burn patients with or without infection. However, certain patterns of clinical signs and symptoms may help recognize the systemic bacterial invasion (Table 76-4).[41]

Biomarkers of Infection and Sepsis

A rise in C-reactive protein serum levels has been found useful in predicting systemic infection, although increases in the first 2 days after the burn or the day after surgery may occur without infection.[99]

Complications of Infection

Other than the primary infection of the burned skin, several types of infectious complications in burn patients have been recognized. Bacteremia is a frequent complication. When sepsis occurs, it is preceded by increased C-reactive protein about 2 days before the patient exhibits signs of clinical sepsis. Another important biomarker is serum procalcitonin. Its relatively early rise within 4 hours of response to infection or trauma, with a long plateau of up to 24 hours, makes this marker very valuable in early assessment of sepsis. Nonetheless, the lack of widespread availability of procalcitonin assay limits its usefulness in clinical practice. Elevated levels of certain cytokines may also be useful biomarkers of infection, but they largely remain research tools. Burn wound manipulations are responsible for development of bacteremias in approximately 50 percent of cases, but routine instrumentation and intravascular catheter devices also can cause bacteremia.[14,50] The risk for developing bacteremia also correlates with the TBSA affected by burns; Sasaki and associates showed that those patients with a positive blood culture had an average TBSA injury of 47 percent, whereas those with a 26 percent injury had negative blood cultures.[116] Bloodstream infection has been associated with longer duration of hospitalization and mechanical ventilation but not with mortality.[19] Toxic shock syndrome caused by TSS toxin–producing strains of *S. aureus* has been identified in acutely burned children. Childs and coworkers found that 13 percent of children developed a toxic shock–like illness; however, its effect on overall burn mortality was not clear.[23]

Subacute bacterial endocarditis is a risk associated with persistent bacteremia caused by any cause, including repeated instrumentation, surgical intervention, and placement of central venous catheters.[13,21] *S. aureus* and gram-negative bacilli are the most frequent cause. In most cases, the antemortem diagnosis rarely is suspected in children with burn injury.[2,13] In addition to causing local valvular damage, infected vegetations may dislodge septic emboli. Suppurative thrombophlebitis occurs at the site of the insertion of the catheter. It may occur in as many as 5 percent of patients with burns covering 20 percent of the TBSA.[124]

Suppurative chondritis occurs in patients with full-thickness burn of the ear.[91] Because of the auricle's relatively low level of blood supply, chondritis frequently follows the progression of tissue ischemia, usually 3 to 5 weeks after burn injury occurs.[92] *P. aeruginosa* and *S. aureus* are the most common pathogens. However, with use of mafenide acetate as a topical agent, the incidence of suppurative chondritis has decreased significantly.

Suppurative sinusitis is seen in patients with long-term nasotracheal intubation. In one study, 8 percent of patients with burns who had nasotracheal intubation for more than 7 days developed sinusitis.[18] Pneumonia may occur with or without inhalation injury, although those with inhalation injury have a substantially higher risk.[122] Bronchopneumonia is the most common type of pulmonary infection, usually occurring in the second week of burn injury. Predisposing factors are size of the burn wound (hematogenous spread), aspiration, presence of tracheostomy or nasotracheal tube (nosocomial spread from burn wound), existence of inhalation injury, and disturbances of fluid and electrolyte balances. Causative organisms include gram-positive bacteria, especially *S. aureus;* gram-negative organisms such as *P. aeruginosa*, *E. coli*, and *K. pneumoniae;* and viruses, including HSV and CMV. Currently, most infection-related deaths in burn patients are caused by pneumonia or bloodstream infections, rather than wound infection.[122] Fatal viral pneumonia due to CMV and HSV has been described as well.[26]

Urinary tract infection occurs in association with prolonged and often unnecessary catherization.[117] Osteomyelitis can occur when bones are exposed by the burn

or by open fracture accompanying the burn; from extension of infection from a septic joint, introduction of organisms along traction pins, and internal fracture fixation devices; or by bacteremia. However, clinically significant osteomyelitis in burn patients is rare.[34] Septic arthritis occurs when a joint is exposed by a burn or by removal of burn eschar.[34] The joints most frequently exposed are the knee, the elbow, the proximal interphalangeal joints of the hand, and the metacarpophalangeal joints on the dorsal surfaces of the hand. The incidence of septic arthritis is obscured by its frequent association with signs and symptoms of severe burns that rarely are separable. Rarely in burns, a joint may become infected from adjacent metaphysical osteomyelitis. In children, most joints can be salvaged. Adult joints are less resilient.

Central nervous system infections in burn patients include meningitis, microabscesses, and septic infarcts. In one review, *Candida* spp., *S. aureus*, and *P. aeruginosa* caused almost 80 percent of infections, occurring most frequently in patients with extensive burns with wound infection or endocarditis.[140]

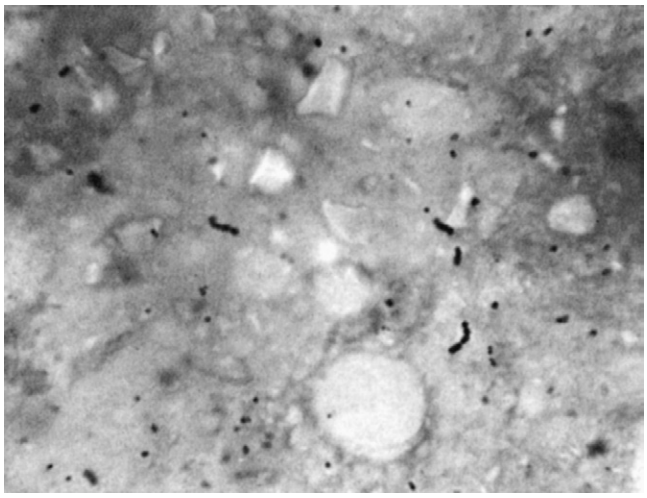

FIGURE 76-2 ■ Photomicrograph of a homogenized biopsy specimen stained with Gram stain. Gram-positive cocci are seen (cultures grew group A streptococcus at greater than 10^5 colony-forming units/gram tissue). (Reprinted with permission from Hunsicker L, Heggers JP, Patel JA. Infections in burn patients. In: Patrick CC, editor. *Clinical management of infections in immunocompromised infants and children.* 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2001. p. 338.)

MICROBIOLOGIC INVESTIGATIONS

The three major approaches to determine burn wound infection are (1) quantitative burn wound cultures, (2) histologic assessment of bacterial invasion, and (3) bronchoalveolar lavage (BAL).

Quantitative Burn Wound Cultures by Biopsy

Teplitz demonstrated that quantitative bacterial counts of burn wound cultures correlated with histologic specimens showing invasion or colonization.[127] Burn wound infection (often referred to as "burn wound sepsis" in surgical literature) is suspected when proliferating microorganisms exceed 10^5 per gram of tissue and when invasion of subjacent unburned tissue has occurred (Fig. 76-2). The presence of microorganisms within the necrotic eschar cannot be considered evidence of burn wound infection. Furthermore, although a bacterial count of 10^5 per gram of tissue is likely to indicate bacterial invasion, this is not invariably true. Only the histologic sections can indicate the level of infection. Therefore, burn wound cultures always should be accompanied by histologic sections from the same area.[108,109]

At the time that surgery is performed, the potentially infected tissues should be excised with a punch biopsy (Fig. 76-3) and divided into equal aliquots.[55] One aliquot should be placed into saline and delivered to the microbiology section for quantitative assessment. These biopsy samples are weighed aseptically and homogenized in a sterile tube in 3 mL of sterile saline. Known dilutions of the homogenate then are plated using precalibrated loops (10 μL) onto blood agar, colistin-neomycin agar, MacConkey agar, and Sabouraud agar for identification in initial dilutions of 0.1 mL with a 1-mL sterile pipette. After 24 hours, the number of colonies are counted and

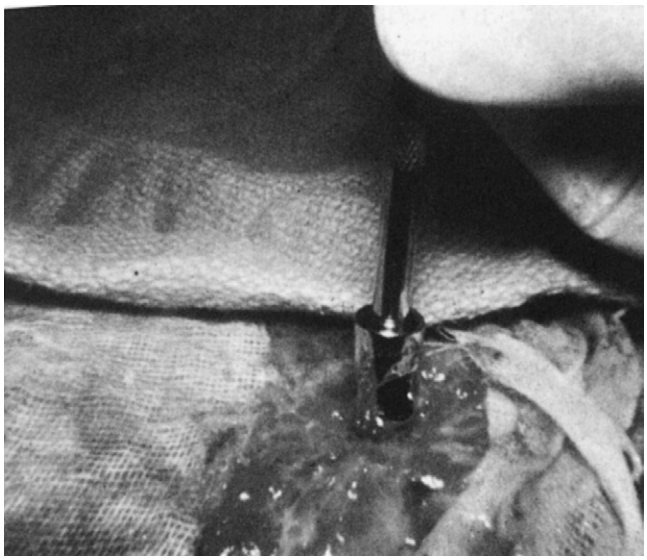

FIGURE 76-3 ■ Photograph showing the use of a 6-mm punch for collecting a skin biopsy specimen for tissue histology and quantitative culture. (Reprinted with permission from Hunsicker L, Heggers JP, Patel JA. Infections in burn patients. the quantitative wound culture is calculated according to the following formula:

$$\text{Colony-forming unit (CFU)} \times \text{g of tissue} \times \text{number of colonies} \times \text{volume} \times \text{dilution weight of biopsy in grams}$$

Despite the dependence on quantitative tissue cultures, reliability of this procedure has been questioned because of the high degree of variability in quantitative

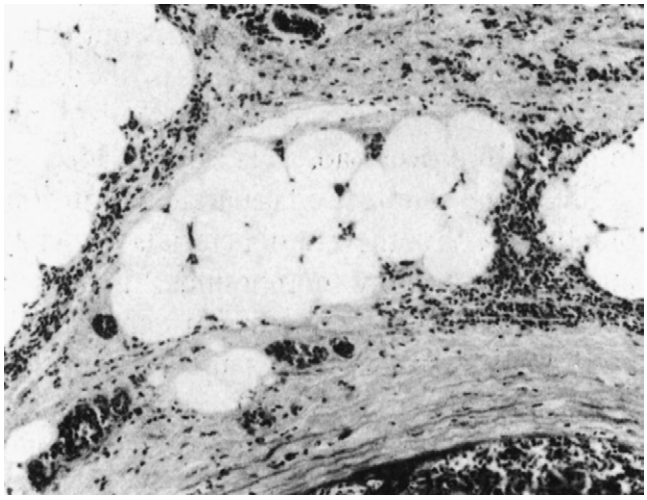

FIGURE 76-4 ■ Photomicrograph of a cross-section of tissue stained with hematoxylin and eosin showing invasion of *Pseudomonas aeruginosa.* (Reprinted with permission from Hunsicker L, Heggers JP, Patel JA. Infections in burn patients. In: Patrick CC, editor. *Clinical management of infections in immunocompromised infants and children.* 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2001. p. 338.)

counts. Woolfrey and colleagues found that when biopsy samples were divided and cultured separately, only 38 percent of paired quantitative results agreed within the same $\log_{10}$ unit, whereas 44 percent differed by 2 $\log_{10}$ units or more.[141]

Histologic Procedures

Standard histologic procedures, as well as cryostat examination, are necessary.[109] The tissues should be examined for morphologic changes and for the presence of pathogens. Many bacterial and fungal pathogens can be identified by staining with Gram stain and Gomori methenamine silver stain (Fig. 76-4). More specialized stains may be necessary to identify other fastidious bacteria and fungi. Tzanck stain can be used to identify inclusion bodies suggestive of invasion of HSV or VZV. Viral-specific antibodies also can be used to detect these viruses by immunohistochemistry. The microbial status of the burn wound (i.e., colonization or invasion), as assessed by histologic examination of a biopsy specimen, can be graded on the basis of the density and depth of penetration of microorganisms (Table 76-5).[109]

Bronchoalveolar Lavage

BAL fluid needs to be collected by personnel experienced in the evaluation of patients with inhalation injury who are at risk for developing airway edema and obstruction. Ventilator-associated pneumonia can be diagnosed if 10^4 or more organisms per milliliter are cultured. In a study reported by Wahl and colleagues, BAL eliminated the unnecessary antibiotic treatment of 21 percent of patients.[133] In winter months, BAL fluids also can be processed for prevalent respiratory viruses such as respiratory syncytial virus (RSV), influenza A and B viruses, and adenoviruses by rapid antigenic detection by immunoassays that are within the capability of most laboratories. Other respiratory viruses, as well as herpesviruses such as HSV and CMV in the respiratory tract, may be detected by viral culture or molecular diagnostics performed by a specialized virology laboratory or reference laboratory.

TABLE 76-5 **Staging of Microbial Status of the Burn Wound by Biopsy Histology**

Stage I: Colonization

A. Superficial: microorganisms present only on burn wound surface
B. Penetrating: variable depth of microbial penetration of eschar
C. Proliferating: variable level of microbial proliferation at nonviable-viable tissue interphase (subeschar space)

Stage II: Invasion

A. Microinvasion: microorganisms present in viable tissue immediately subjacent to subeschar space
B. Deep invasion: penetration of microorganisms to variable depth and expanse within viable subcutaneous tissue
C. Microvascular involvement: microorganisms within small blood vessels and lymphatics (thrombosis of vessels common)

Modified from Pruitt BA, Foley FD. The use of biopsies in burn patient care. *Surgery* 1973;**73**:887-97.

Local and Systemic Viral Infection

Viral culture or molecular testing using qualitative or quantitative PCR of the wound surface obtained by swab or by tissue obtained by biopsy will detect the presence of HSV or VZV. Disseminated viral infection with HSV, VZV, CMV, and other viruses may be evaluated by sending whole blood or plasma for specific viral DNA detection and quantification by PCR.

PREVENTION AND TREATMENT OF INFECTION

Care of the wound is the mainstay of burn therapy. The goal is to minimize infection and facilitate healing of the burn wound. Wound care addresses both partial- and full-thickness burn injuries until all wounds are closed.

Wound Dressing

The superficial epidermal layer provides a barrier to microorganisms while the deeper lipid epidermal layer provides protection against loss of water vapor. In full-thickness burns, the eschar may extend beyond the skin into the subcutaneous fat and muscle. Closure of the wound cannot occur until the eschar is removed. Bacterial proteases lead to eschar pseudoseparation and are slowed with antiseptic therapies. Then, the eschar is allowed to fragment and slough, with resultant decreased size. This process is called *wound contraction*. This can also be excised and skin grafted. Full-thickness skin grafts have the least contraction rates. Deep dermal wounds

allowed to heal spontaneously lead to hypertrophic scarring. Compression garments are used for prevention and treatment.

When approaching burn wound care, a plan must first be decided. Outer burn dressings provide comfort, metabolic enhancement, and protection. First, superficial burns are exquisitely sensitive to air currents, as are deeper burns after some healing. Also, dressings provide splinting and drainage containment. Next, occlusive dressings help eliminate shivering, cold stress, and evaporative heat loss. In open, granulating wounds, loss of water vapor is maximal. Finally, the protective component deals with the control of topical organisms. Supplies consist of large 9 × 9-inch burn gauze, Kerlix wraps, Ace wraps, and topical antimicrobial agents. Gentle cleansing of the wound and daily débridement also are important. Buttock burn wounds should be examined carefully and frequently for the presence of deep stool staining, an ominous predictor of burn wound sepsis and death.[112] Such wounds should be emergently excised.

Topical Antimicrobial Agents

Topical antimicrobial agents are used extensively in burn patients. Most patients with stage I and stage II A and B wounds (see Table 76-5) can be treated with topical or subeschar antimicrobial agents alone.

Silver Sulfadiazine (Silvadene, SSD, Thermazene, Flamazine, Burnazine)

Silver sulfadiazine is a 1 percent water-soluble cream combining sulfadiazine with silver (Ag^+). The Ag^+ ion binds with the DNA of an organism and consequently releases the sulfonamide that interferes with the intermediary metabolic pathway of the microbe. It is most effective against *P. aeruginosa*, the gram-negative enteric bacteria, and *C. albicans*. *S. aureus* and some strains of *Klebsiella* spp. have been less effectively controlled.[41] Caution is advised with use of sulfadiazine products because cases of *P. aeruginosa* resistance to sulfadiazine have been reported.[54] When compared with collagenase ointment, topical silver sulfadiazine has been shown to be associated with lower rates of wound infection.[105] Antimicrobial effectiveness has been observed to last for up to 24 hours. More frequent changes are required if a creamy exudate forms on the wound. The benefits of this topical agent are its ease of use and its ability to reduce pain. It has some tissue-penetrating ability, but it is limited to the epidermis.

Silver sulfadiazine can be used separately or in combination with other antibacterial agents or enzymatic escharotomy compounds. It can be combined with nystatin, which enhances the antifungal activity of this agent. By itself, silver sulfadiazine has been shown to retard wound healing; however, in conjunction with nystatin or aloe vera, the wound-retardant effect is reversed. When topical silver sulfadiazine was compared with the more expensive collagenase ointment for treatment of partial thickness burns in children, there was no significant difference in clinical course, outcome, or need for skin grafting.[105]

Cerium Nitrate–Silver Sulfadiazine (Flammacerium)

The lanthanide salt cerium nitrate has been added to silver sulfadiazine since the 1970s and has been shown to have increased bacteriostatic effect in large burn wounds. The antimicrobial spectrum is similar to that of silver nitrate. Methemoglobinemia has been seen only rarely, and no associated electrolyte disturbances occur. Only minimal cerium absorption has been noted in patients with large burns treated for weeks. No complications were noted. Its use is somewhat limited because it is not commercially available in the United States. It is, however, available in several western European countries. Koller and Orsag studied the effects of cerium sulfadiazine in 20 burn patients and found it to be safe and effective in the treatment of deep, extensive burn wounds.[73]

Silver Nitrate

Silver nitrate is available as a 0.5 percent solution that does not injure the regenerating epithelium in the wound and provides bacteriostatic effect against *S. aureus*, *E. coli*, and *P. aeruginosa*.[41] Silver nitrate is most effective when the wound is cleansed carefully of all emollients and other debris. Multilayered coarse mesh dressings should be placed over the wound and saturated with the silver nitrate solution. Like silver sulfadiazine, silver nitrate has limited penetration because the Ag^+ ion is bound rapidly to the body's natural anions such as Cl^-. Because it is hypotonic, it can cause osmolar dilution, resulting in hyponatremia and hypochloremia. Serum electrolyte levels should be monitored very carefully.

Notable detriments to the use of silver nitrate include its high expense and light sensitivity. Furthermore, it also requires special handling because if it is allowed to dry or if it is covered with an impervious dressing hyperpyrexia could occur. *Klebsiella*, *Providencia*, and other Enterobacteriaceae are not as susceptible to it as are other bacteria. *E. cloacae* and other nitrate-positive bacteria can cause methemoglobinemia by converting nitrite to nitrate.

Mafenide Acetate (Sulfamylon)

Mafenide acetate is available both in a 10 percent water-soluble cream or a 5 percent solution and has more substantial bacteriologic data to support its efficacy than do any of the other topical antimicrobial agents.[76,89] It has been shown to be effective against a broad range of microorganisms, especially against all strains of *P. aeruginosa* and *Clostridium* spp.[116] After a wound has been cleansed of debris, mafenide acetate is applied to the wound like "butter." The treated burn surface is left exposed for maximal antimicrobial potency. The cream is applied a minimum of twice a day and can be reapplied as needed. The 5 percent solution is applied every 8 hours.

Additionally, mafenide acetate has the ability to permeate burn eschar and thereby reduce the risk for bacterial colonization of a deep burn wound, and it is especially effective after the dead tissue is removed from the

granulating bed. Unfortunately, several detrimental aspects are associated with the use of mafenide acetate. Protracted use with the low environmental pH favors the growth of *C. albicans.* Mafenide acetate is converted to *p*-sulfamoyl benzoic acid by monamine oxidase, which is a carbonic anhydrase inhibitor; it subsequently causes metabolic acidosis in the patient. It also is painful when applied to superficial, partial-thickness burns with intact free nerve endings, and its requirement to remain uncovered for antimicrobial activity may be considered a disadvantage when a dressing is required.

Membrane Dressings

Acticoat and Aquacel are silver-coated dressings that have a broad antibacterial activity. Compared with silver nitrate or silver sulfadiazine use, Acticoat and Aquacel have been found easier to apply, were associated with less pain on removal, and have faster rates of reepithelialization.[22,128] In one clinical study, Acticoat was found to have better antibacterial activity than silver sulfadiazine.[70] Acticoat is also better than hydrogel (Solosite) and paraffin-embedded woven cotton fabric (Jelonet) in protection against wound colonization/infection.[134] Mepitel is another grid-like, silicone-coated, nylon dressing used in treatment of partial-thickness burn wounds. Gotschall and associates found this product to decrease the pain experienced during dressing change, the time needed for the wound to heal, and the overall duration of the hospital stay as compared with silver sulfadiazine.[46] This study did not find any difference in the incidence of infections between Mepitel and silver sulfadiazine treatments.

Topical Antibiotics

Several topical antibiotics have been tried in the management of burn infections. The use of these agents is highly discouraged in a burn unit because of rapid emergence of resistance:

1. *Gentamicin sulfate:* Available as a 0.1 percent water-soluble cream, this antibiotic is chemically similar to the other aminoglycosides, such as kanamycin and neomycin. It has a broad spectrum of antimicrobial activity. It is used for its activity against *P. aeruginosa;* however, its topical use is highly limited because of the high level of gentamicin resistance in burn units.
2. *Bacitracin/polymyxin:* This antibiotic combination has little or no effect on localized infections of burn wounds.
3. *Nitrofurantoin:* This agent is used topically as adjunctive therapy in patients with second- and third-degree burns. With good eschar penetration, it can be used in the treatment of invasive burn wound infections with sensitive agents. The drug presents some advantages for the ambulatory patient. Tissue granulation begins sooner and crusts separate more rapidly.
4. *Mupirocin (Bactroban):* Studies at Shriners Hospitals for Children–Galveston have shown mupirocin to be superior to silver sulfadiazine in treating MSSA or MRSA infection.[125] Although mupirocin is weaker against gram-negative bacteria, it is also comparable to silver sulfadiazine and mafenide acetate against *P. aeruginosa*, *E. coli*, and *K. pneumoniae.*

Nystatin (Mycostatin, Nilstat)

Studies have shown that combining nystatin and silver sulfadiazine or nitrofurantoin results in effective prevention of local and systemic *Candida* infections, as well as burn wound sepsis.[56] However, in combination therapy with silver sulfadiazine and nystatin, mafenide acetate actually loses its antimicrobial activity. Therefore, use of nystatin with mafenide acetate is discouraged. Concentrated nystatin powder has also been studied for its effects on angioinvasive fungi (e.g., *Fusarium*, *Aspergillus*) refractory to systemic amphotericin B and serial excisions, including amputations.[11] A concentrated form of nystatin (6 million units/g) was used as dry aerosol every 6 hours and wet to dry dressings laid on top. Within 14 days, in all four of the children studied eradication occurred of their invasive fungal infections. Also, all areas previously autografted underneath the nystatin powder healed nicely.

Sodium Hypochlorite (0.025% Heggers Solution)

Currently, the most effective topical antibacterial agent for cleansing a wound is sodium hypochlorite (NaClO). It transcends the topical antimicrobial effects and tissue toxicity of such products as povidone-iodine, acetic acid, and hydrogen peroxide. The efficacy of NaClO has been determined to be at a concentration of 0.025 percent, which is bactericidal, is nontoxic to fibroblasts, and does not inhibit wound healing, provided buffers are used.[57] It is a broad-spectrum antiseptic and is bactericidal for *P. aeruginosa*, *S. aureus* (MRSA and MSSA), enterococci, and other gram-negative and gram-positive organisms.[116]

Povidone-Iodine (Betadine)

The active antimicrobial component in this compound is the iodine. It has a broad spectrum of antibacterial and antifungal activities. However, there are disadvantages that limit its use in a burn center. It is painful when applied and is inactivated by wound exudates. Renal dysfunction and acidosis have been noted in association with systemic absorption when applied to open wounds.

Chlorhexidine

Chlorhexidine when combined with 0.5 percent silver nitrate has efficacy similar to that of silver sulfadiazine.[80] Some variants of this product have broader antimicrobial activities, but pain experienced by patients on application has limited its use. Unlike the sulfonamides, plasma-mediated resistance has not occurred.

Citric Acid

In a study from India,[98] citric acid was formulated into a 3 percent gel and was compared with silver sulfadiazine. Citric acid gel application was better in wound healing. However, large-scale studies are lacking.

Subeschar Antibiotics

Moncrief has described the technique of subeschar antibiotic infusion.[92] It is used for microbial invasion into unburned tissue, when topical therapies have not been effective, or in cases in which treatment has been delayed. The most common drugs used are tobramycin, gentamicin, and kanamycin. However, development of antimicrobial resistance is likely to be substantial, so subeschar infusion of antibiotics should be used infrequently. The antibiotic solution is administered via multiple needle infusions by subcutaneous lysis. The results of this technique are more rapid separation of eschar. The fluid infusion limit is 2000 mL (adult dose) and should be accounted for in a patient's fluid requirements. The infusion fluid should consist of 0.25 to 0.45 N saline to avoid salt overload. Use of lactated Ringer solution should be avoided because some of the drugs are incompatible with calcium. Erythromycin has been studied but is too painful to use. Colistin, novobiocin, and cephaloridine have been used but found to be ineffective.

Systemic Anti-infective Agents

Drug pharmacokinetics are significantly altered in the burn patient and show significant interpatient and intrapatient variation.[137] Dolton and coworkers showed that vancomycin clearance is significantly higher in burn patients, but there is no significant difference in the volume of distribution.[31] Doh and associates also showed that meropenem clearance and volume of distribution were higher.[30] These studies suggest that higher dosing of vancomycin and meropenem may be needed in burn patients. Despite these studies, however, a review of the currently available literature shows that for many drugs there is a paucity of information to support current dosage recommendations, specifically in children of various age groups. In addition, many reports are based on small numbers of patients, and even in larger studies, no standardization of the study population exists with regard to the important variables known to affect drug handling. For the subpopulation of burn patients who eliminate drugs extremely rapidly, a concern exists over the adequacy of antibiotic dosing. Researchers have suggested that antibiotic serum concentrations be measured, when available, in every patient to ascertain whether a significant problem exists with dosing.

Whereas stage I and stage II A and B wounds (see Table 76-5) can be treated with topical or subeschar antimicrobials alone, stage II C wounds require the immediate institution of systemic anti-infective agents. Systemic agents also are indicated for the treatment of various systemic infectious complications (see earlier discussion). Detailed information on selection of the appropriate systemic antimicrobial agents for specific bacterial, fungal, and viral pathogens is available elsewhere in this text. Nonetheless, the following general principles can help guide the use of antimicrobial therapy:

1. Each antimicrobial agent must be selected for its specificity for the microbe present.
2. Such decisions should be made on appropriately collected culture and susceptibility data.
3. Colonizing flora should be distinguished from those responsible for inflammation and invasion.
4. The time, dosage, route of administration, and duration of treatment should be in accordance with what is required to make the organism nonpathogenic.
5. The need for broad-spectrum antibiotics should be balanced with the risk for promoting fungal infections.

Treatment of Multidrug-Resistant, Gram-Negative Bacteria

This issue deserves specific mention because it most severely affects the burn units. In many centers, panresistant *P. aeruginosa* strains and *Acinetobacter* spp. are identified frequently. In these cases, colistin and polymyxin B often remain the only susceptible antimicrobial agents. In a recent study, Goverman and coworkers summarized their experience in 14 children treated with intravenous colistin: a favorable response was obtained in 79 percent, and the overall mortality rate was 14 percent.[47] Both colistin and polymyxin B are associated with significant elevation in serum creatinine value or with renal failure in 15 to 25 percent of recipients. Neurotoxicity in children is an infrequent occurrence. Intravenous and/or aerosol polymyxin B, doxycycline, and ampicillin/sulbactam (the active component is thought to be sulbactam) have been tried in multidrug-resistant *Acinetobacter* infections as well.[101] Other studies have demonstrated in vitro susceptibility of multidrug-resistant *Acinetobacter* to various synergistic combinations of antimicrobial agents, including carbapenems, colistin, rifampin, tigecycline, and ampicillin-sulbactam.[44,59,142] The clinical utility of these combinations against panresistant *Acinetobacter* remains to be determined.

Treatment of Viral Infections

If herpes simplex virus or varicella zoster virus infection of the wound surface, lungs, or disseminated viral infection with viremia is present, then systemic antiviral treatment with acyclovir is indicated. Pneumonitis and systemic infection with significant viremia with CMV should be treated with ganciclovir. If viral resistance to first-line antiviral agents occurs, then foscarnet or cidofovir may be administered. Respiratory tract infection, including pneumonia, associated with influenza A or B virus may be treated with oseltamivir, which can be orally administered if the patient is able to absorb enterally administered medications.

Antibiotic Prophylaxis

Prophylactic use of antibiotics remains a highly controversial topic. Penicillin prophylaxis is used commonly in many burn centers during outbreaks of group A streptococcal infections.[49,113] Prophylactic antibiotics also are used before surgical manipulation or instrumentation because the risk for developing bacteremia is as high as 50 percent. The choice of perioperative antibiotics is dependent on the knowledge of existing microorganisms,

which are present not only on injured skin but also in the wound that is ready for surgery. Nonetheless, carefully controlled studies are necessary to identify the value of prophylactic antibiotics. In a placebo-controlled study of cefazolin use in children with burn injury, researchers found that in children with burns of less than 35 percent TBSA, cefazolin was not necessary, and in those with burns of 35 percent or more, it was not effective.[114] In a retrospective review study, antibiotic prophylaxis was not associated with any reduction in the rate of wound infection; instead, the duration of hospitalization was found to be longer.[32] A recent meta-analysis of studies of prophylactic antibiotics found that most of the studies were weak.[5] The most important finding was that staphylococcal infection rates declined with prophylaxis but resistance to prophylactic antibiotics increased.

Wound Excision and Grafting

Studies have shown that early excision of wounds leads to significantly decreased rates of bacterial colonization and wound infection.[10] In a meta-analysis of six trials it was found that early excision of burns is beneficial in reducing mortality (in patients without inhalational injury) and length of hospital stay. The only drawback is the greater volume of blood loss.[103]

Gut Support and Decontamination

The gut microflora have been implicated in the development of multiorgan failure when the gut barrier fails. Hence, one theory is that early enteral feeding of the gut, which promotes function of the gut barrier, is important for preventing multiorgan failure. A decontaminated gut with nonabsorbable, broad-spectrum antibiotics might diminish the impact of failure of the gastrointestinal barrier. Although the suggestion has been made that the rate of pneumonia may be decreased by such maneuvers, no apparent impact on mortality rates has been noted.[85] Overall, convincing human data on the beneficial effect of enteral feeding and decontamination of the gut on sepsis and multiorgan failure are lacking.

Immunomodulators

In view of the intricate relationship between altered immune defenses in burn patients and increased susceptibility to infections, various types of immunotherapies have been tried. In an Italian study, treatment with intravenous pooled immunoglobulin (IVIG) was found to have a beneficial effect on septic phenomena and recovery.[90] However, in two U.S. studies, no change in rates of infection or mortality was shown. Overall, the beneficial role of IVIG as prophylaxis or treatment remains unproven.[97,135] In a German study, prophylaxis with intravenous anti-*Pseudomonas* immunoglobulin did not appear to be beneficial to burn patients in general; however, it was shown to be effective in burn patients with inhalation injury.[126] In a South African study, prophylaxis with high-titer anti-lipopolysaccharide immunoglobulin G reduced the incidence of burn wound infection but did not affect mortality.[64] Benefits of plasmapheresis or fresh frozen plasma infusion have not been proven.

INFECTION CONTROL

Hospital-acquired infections in burn patients are common occurrences. In pediatric burn patients, wound infections, ventilator-related pulmonary infections, central-line bacteremias, and catheter-associated urinary tract infections are the most common nosocomial infections.[117,136] The rates of infections may be lower than those seen in adults, but urinary tract infections occur more frequently in children.[117] In a German study of children with burns, the overall infection rate was 59.7 nosocomial infections per 1000 inpatient-days and the device-associated infection rates per 1000 device-days were 55.2 for pneumonia, 8.9 for primary bloodstream infections, and 41.7 for urinary tract infections.[43] The incident density of burn wound infections was 18.5 per 1000 inpatient-days, which was associated with the percentage of TBSA of the burn wound. On the other hand, the rate of device-associated infections was not associated with the percentage of TBSA.

Surveillance of infection in a burn patient is performed to implement prompt treatment on the basis of surveillance cultures and antimicrobial sensitivities at the earliest sign of invasion. Such surveillance requires cultures of sputum, urine, and wounds about three times weekly; however, the need for such cultures and the frequency of monitoring remain controversial. Additional infection control measures involve surveillance of spread of pathogens among burn patients in a burn unit. In dealing with the burn wound, strict infectious disease precautions must be maintained to prevent contamination and worsening infection in these already immunocompromised patients.

In the past, poor hand washing and shared hydrotherapy tubs were the source of many infections, some of which were life threatening. Strict enforcement of hand washing and use of gowns, gloves, and masks have led to decreased rates of patient contamination. Also, disposable hydrotherapy tub liners are used without the risk for patient-to-patient transmission of infections.[129] Besides this, isolation of burn patients in a single room compared with placing them in an open ward has dramatically affected infection rates. McManus and associates studied this measure in 2519 patients and found significantly lower incidence and mortality rates associated with gram-negative bacteremia in the isolated patients.[88] Also, the patients in an open ward with bacterial isolates showed significantly more antimicrobial resistance compared with patients in isolation.

Additional infection control measures include the daily use of germicidal solutions to clean all of the hardware, such as intravenous poles and pumps, monitoring equipment, bedside tables, and beds in patients' rooms. On discharge of the patient, everything in the room, including floors, walls, ceilings, and mattresses, needs to be cleaned with germicidal solutions. Air filters should be monitored repeatedly for fungal and bacterial growth.

Lai and colleagues studied the effects of strict isolation of patients with vancomycin-resistant enterococci, the use of vancomycin, and the cost-to-benefit analysis of barrier precautions.[77] The study showed that pharyngeal swabs were poor for surveillance but that rectal swabs were more useful. Also, guidelines for use of vancomycin were adhered to by 85 percent of the staff. The overall cost for these implementations, including the barrier supplies and cleaning protocols, was $11,000. Nonetheless, vancomycin-resistant enterococci were not eradicated. On the other hand, van Rijn and colleagues[131] have shown that isolation in a quarantine unit was highly effective in preventing outbreaks of multidrug-resistant bacteria.

SECTION XV

UNCLASSIFIED INFECTIOUS DISEASES

CHAPTER 77

Kawasaki Disease

Stanford T. Shulman

Kawasaki disease is a multisystem acute febrile vasculitic syndrome of presumably infectious origin that affects predominantly infants and young children. The diagnosis is based on characteristic clinical features (Table 77-1). Serious complications include coronary arteritis, coronary artery aneurysms and stenoses, coronary thrombosis leading to myocardial infarction, and, very rarely, rupture of a coronary aneurysm. Kawasaki disease has become the leading cause of acquired heart disease in children in most developed countries including the United States and Japan.[386,387] It has been reported in children of all racial groups and from all continents. Although the etiology of Kawasaki disease remains unknown and a specific diagnostic test is lacking, establishing a timely diagnosis is very important because administration of intravenous immunoglobulin (IVIG) and aspirin before the 10th day of illness generally has a dramatic effect on the clinical manifestations and markedly reduces the likelihood of development of coronary abnormalities (see the later sections on treatment).*

Synonyms for Kawasaki disease include *Kawasaki syndrome* and *mucocutaneous lymph node syndrome* (MCLS, MLNS, or MCLNS). The disease also has been referred to as *lymphomucocutaneous syndrome*. An earlier term used in autopsy reports was *infantile periarteritis nodosa* (IPAN), which is pathologically indistinguishable from fatal Kawasaki disease. The International Classification of Diseases (ICD-9) designates the condition as both Kawasaki disease and mucocutaneous lymph node syndrome (acute) (febrile) (infantile) under rubric 446.1. Before 1983, the National Library of Medicine listed Kawasaki disease publications under various subject headings, particularly "Lymphatic Diseases." Since 1984, publications have been listed under "Mucocutaneous Lymph Node Syndrome," a name that has been replaced by Kawasaki disease.

HISTORY

The illness now bearing his name was first recognized as a clinical entity in 1961 by Dr. Tomisaku Kawasaki, who subsequently became chairman of the Department of Pediatrics at Tokyo's Japan Red Cross Medical Center. Between 1961 and 1967, Kawasaki identified 50 infants and young children who manifested a distinctive constellation of signs that included prolonged high fever, unilateral cervical lymphadenopathy, bilateral conjunctival injection, a polymorphous erythematous rash, changes of the mucosa of the upper respiratory tract, and edema and erythema of the extremities, with subsequent desquamation of the finger and toes. Although the syndrome was distinctive, its signs were nonspecific. Laboratory tests ruled out other disorders. A series of the first seven cases was presented by Kawasaki at the 61st Chiba General Meeting of the Japan Pediatric Society in 1962.[163] Convinced that he was observing a distinct clinical syndrome, Kawasaki published a report of his experience with 50 cases of "febrile oculo-oro-cutaneo-acrodesquamatous syndrome with or without acute nonsuppurative cervical lymphadenitis" in 1967.[164,165,167] Other Japanese physicians quickly recognized the syndrome after Kawasaki's report, although considerable discussion ensued about whether it was a distinct entity or an illness related to Stevens-Johnson syndrome.[166]

Cardiac involvement in this illness was suspected first in 1968, when Yamamoto and Kimura reported an infant with Kawasaki disease who had transient tachycardia with a gallop rhythm, cardiomegaly, and minor electrocardiographic (ECG) abnormalities.[422] In 1970, Kawasaki obtained funding to establish the Research Committee of Mucocutaneous Lymph Node Syndrome, sponsored by the Japanese Ministry of Health and Welfare, which was organized with Dr. Fumio Kosaki as chair.[167] In the first national survey of this committee, four autopsied and six nonautopsied cases of children who had died of coronary artery complications after apparent Kawasaki disease were identified.[182] These children were predominantly younger than 2 years of age and had died suddenly within 30 days of onset of disease, with evidence of coronary aneurysms and acute thrombosis. The first biennial Japanese national epidemiologic survey was conducted by this committee in 1970 under the leadership of Dr. I. Shigematsu and was published in 1972.[336] By this time, it had become well established that some patients who recovered apparently uneventfully from this acute illness were at risk for sudden cardiac death, with findings of acute myocardial infarction secondary to thrombosis within coronary arteries damaged by a severe vasculitic process.[182]

In 1971, physicians at the University of Hawaii who were unaware of the Japanese experience began to recognize patients with an unusual Reiter syndrome–like illness. When information about Kawasaki disease was published in the English-language literature,[167] the illness in Hawaii was recognized clearly as Kawasaki disease. Information exchanged between Japanese and U.S. investigators led to the 1974 publication of English-language articles by both groups[167,228,229] and triggered worldwide recognition of cases. In the early 1970s, death

TABLE 77-1 Diagnostic Criteria for Classic or Typical Kawasaki Disease

Fever for at least 5 days*
plus
Presence of four of the following features:
Bilateral conjunctival injection
Polymorphous exanthem
Changes in the lips and oral cavity (erythema, cracking of lips; oropharyngeal erythema; strawberry tongue)
Peripheral extremity changes (erythema and swelling of hands and feet; later periungual desquamation, Beau lines)
Cervical lymphadenopathy (≥1.5 cm in diameter)
Exclusion of other diseases with similar features

Note: The finding of fever plus three criteria in the presence of coronary abnormalities qualifies.
*In the presence of classic features, experienced clinicians may be able to establish the diagnosis before the fifth day of illness.

from myocardial infarction was reported to occur in approximately 2 percent of cases of Kawasaki disease; more recent data reflect much lower mortality rates of less than 0.02 percent.[124,251,408,428] Seven deaths were recorded in Japan among 47,067 patients in 2007 to 2010 (0.014%). With the availability of echocardiography in the late 1970s, researchers determined that 20 to 25 percent of patients developed evidence of coronary artery abnormalities.[153]

In the decades before Kawasaki recognized the clinical features of the illness, many individual reports of fatal coronary arteritis in children (usually labeled IPAN) were published in the non-Japanese pediatric and pathology literature.* Clinical details of these cases generally are highly suggestive of Kawasaki disease, and the pathologic features of IPAN are indistinguishable from those of Kawasaki disease, as demonstrated conclusively by Landing and Larson in 1977.[189] Almost 100 years before Kawasaki's description was published, Samuel Gee of St. Bartholomew's Hospital in London in 1871 reported the case of a 7-year-old boy who at death ("following scarlatinal dropsy") had three coronary aneurysms, each filled with a fresh clot; histologic examination of that patient's cardiac tissue is compatible with inactive Kawasaki disease with extensive coronary myointimal proliferation and fibrosis.[108,345] Shibuya and colleagues retrospectively identified cases of illnesses compatible with Kawasaki disease that occurred in Japan up to 2 decades before Kawasaki's description was published.[335] Likely, patients with Kawasaki disease in previous decades were misdiagnosed as having measles, scarlet fever, rubella, or other once common conditions, and reductions in the numbers of cases of those illnesses helped to facilitate recognition of Kawasaki disease.[166]

Kawasaki's clinical description of the syndrome has remained the foundation of diagnosis and the basis of the clinical and epidemiologic case definitions in use today (see Table 77-1). In 2004, the American Heart Association Committee on Rheumatic Fever, Bacterial Endocarditis, and Kawasaki Disease published guidelines for the management of patients with incomplete (or atypical) Kawasaki disease (see later).[262]

*References 55, 83, 242, 284, 298, 305.

EPIDEMIOLOGY

Sources of Epidemiologic Data

As with most notifiable diseases, passive reporting of Kawasaki disease cases is incomplete. Passive surveillance data may help to monitor secular trends and to identify epidemics, but these data are of little value in estimating the true incidence of disease. Outbreak investigations are more sensitive in determining local disease incidence, and they enable investigators to study potential risk factors.

In the absence of a confirmatory diagnostic test, the epidemiologic case definitions of Kawasaki disease are relatively strict and exclude from surveillance data other exanthematous conditions that could dilute "true" cases and thus could obscure secular trends. However, the original epidemiologic case definitions were not intended for clinical application, a very important point since effective treatment became available. Thus, less strict application of clinical case criteria is appropriate for management of patients. Clinicians must be aware that children often present with clinical illnesses that do not completely fulfill the diagnostic criteria for Kawasaki disease but who are nonetheless at risk for developing coronary artery sequelae and therefore warrant therapy. These patients generally are considered to have *incomplete* or *atypical* Kawasaki disease.[28,96,262,317] Incomplete presentations of Kawasaki disease are particularly common occurrences in young infants in whom clinical signs often are subtle or fleeting but who are at the highest risk for development of coronary artery abnormalities.[42,309] In the United States, the Centers for Disease Control and Prevention (CDC) case definition usually is used for epidemiologic purposes and the American Heart Association published an algorithm to aid in the diagnosis of incomplete (atypical) Kawasaki disease.[262] The current Japanese diagnostic guidelines were revised for the fifth time and also reflect the importance of incomplete cases.[17]

Incidence Rates

The incidence of Kawasaki disease varies throughout the world and reflects primarily the racial composition of various countries. Rates in Japan have climbed steadily, with an annual rate of 239.6 per 100,000 children younger than 5 years of age in 2010 (21st national survey).[408] The highest reported rate in Korea was 118 per 100,000 children younger than 5 years old in 2007.[134] In countries with predominantly non-Asian populations, the rate is 15 to 20 per 100,000 children younger than 5 years of age.[133]

Gender

In virtually all population-based studies in many countries, the ratio of male-to-female patients with Kawasaki disease approximates 1.5 : 1.[408,428,430] In addition, serious

and fatal complications also are significantly more common findings among male patients with Kawasaki disease compared with female patients.[251,429] Examination of fatal Japanese cases indicated almost three times as many Kawasaki-related fatalities among male patients compared with female patients, with a higher ratio in infancy.[251,408] The basis for the preponderance of Kawasaki disease in male patients and for the even greater predominance of serious coronary artery disease in male patients with Kawasaki disease remains unclear. Of interest is that a male predominance is observed in many infectious diseases.

Race or Ethnic Background

The first cases of Kawasaki disease were recognized in Japanese children and in Hawaiian children of predominantly Japanese ethnicity, and subsequent data consistently supported higher rates in those of Asian background. Annual incidence rates in Japan have climbed steadily to 239.6 cases per 100,000 children younger than 5 years of age in 2010,[408] from 102.6 in 1995 and 184.6 in 2005 to 2006,[249] and are the highest in the world, approached only by rates for Japanese-American children in Hawaii (210.5/100,000 < age 5 years).[132] More than 12,700 cases of Kawasaki disease were reported in Japan in 2010, with local clusters rather than nationwide epidemics, as were seen in 1979, 1982, and 1985 to 1986.[408] In epidemic years in Japan, the annual age-specific incidence rates reached or exceeded 200 per 100,000 children younger than 5 years of age.[424] Incidence rates in white children in many communities are much lower, most often approximating 10 to 20 per 100,000 children younger than 5 years.[64,133,348] Surveys in countries with almost exclusively white populations often yield rates of 5 to 10 cases per 100,000 children younger than 5 years of age.* In Washington state, ethnic group–specific incidence rates per 100,000 children younger than 5 years of age were estimated to be 33.3 for Asian Americans, 23.4 for blacks, and 12.7 for whites.[64] In Hawaii, with its complex racial-ethnic makeup, the overall annual incidence is about 45 per 100,000 children younger than 5 years of age.[132] The yearly incidence for Japanese children in Hawaii approaches 200 cases per 100,000 children, and for whites it is 35 per 100,000, with intermediate rates for those of native Hawaiian and Chinese, Filipino, and other Asian ancestry.[132] Extrapolation of data from surveys of U.S. hospitals with large children's services led to estimates of approximately 2500 cases per year in the United States from 1984 to 1993,[386,387] with more recent estimates as high as 5000 cases annually.[35] A study of Kawasaki disease in the United States identified approximately 4200 hospitalizations in the year 2000, with highest rates among Asian and Pacific Islanders, lowest rates in whites, and intermediate rates in blacks and Hispanics.[133]

Age

Kawasaki disease occurs almost exclusively in children. In the United States and Japan, adult cases are quite rare, although some reports of adults diagnosed by accepted diagnostic criteria have been published.[195] Many of these adult patients have been infected with human immunodeficiency virus (HIV).* Most of the early reported adult cases, however, probably actually represented toxic shock syndrome or drug hypersensitivity reactions. Perhaps the best-documented adult case (confirmed by Dr. Kawasaki) was that of a 31-year-old Japanese man who later developed bilateral coronary artery aneurysms.[365] Because the signs and symptoms are nonspecific, adults suspected to have Kawasaki disease should be evaluated carefully for infectious, toxic, and other possible causes of illness.

The distribution of Kawasaki disease by age in childhood is highly characteristic. The disease occurs most frequently in young children: 50 percent are younger than 2 years of age, 80 percent are younger than 5 years of age, and cases seldom occur in those older than 12 years of age.[133,357,428] In 2009 to 2010, 0.7 percent of Japanese patients with Kawasaki disease were 10 years old or older.[408] Infants in the first 3 to 5 months of life have a relatively low incidence of Kawasaki disease, but the incidence rises rapidly from that point.[408] In the United States, the peak age is 15 to 18 months, whereas more recent data from Japan identified 25 percent as younger than 1 year old, 88 percent as younger than 5 years, and the peak age incidence as 6 to 11 months of age.[408] In Hawaii, 29 percent of cases are in infants younger than 1 year old and 85 percent of patients are younger than 5 years.[133] The lower peak age in Japan and perhaps in Hawaii may reflect better recognition of Kawasaki disease in infants, in whom Kawasaki disease may be more difficult to diagnose, or it may indicate a biologic difference. The age-incidence curve may be helpful in elucidating risk factors for developing Kawasaki disease. Such a pattern is compatible with highly transmissible infectious agents, particularly respiratory agents, and suggests possible transplacental immunity. The features of 28 patients with Kawasaki disease who were aged 8 years and older at the time of diagnosis at Children's Memorial Hospital in Chicago have been reported.[357] Delays in establishing the diagnosis and in providing treatment were common occurrences and were at least partially related to the prominence of arthritic and gastrointestinal symptoms in this population. I recently cared for a 19-year-old woman with classic Kawasaki disease.

Earlier Japanese mortality data suggested that fatality rates are approximately three times higher in children younger than 1 year old at the time of onset of disease, compared with older children, and that fatalities occur predominantly in the first several months after onset of Kawasaki disease.[427] The overall mortality rate in Japan has dropped from the initial report of approximately 2 percent to more recent Japanese estimates of approximately 0.01 percent.[408] Male patients account for a disproportionate number of deaths in infants and older children.[124,253,408,427] Long-term mortality rates in a large Japanese Kawasaki disease cohort study were increased over background rates, particularly during and shortly after the acute stage of illness.[251,253]

*References 29, 32, 47, 125, 290, 354.

*References 12, 43, 46, 82, 113, 148, 233, 293, 297, 331.

A Taiwanese series of 25 infants who developed Kawasaki disease at 3 months or younger included 19 males and 6 females. Only 6 infants met Kawasaki disease diagnostic criteria, with the other 19 classified as incomplete. Coronary artery involvement was noted in 80 percent, although only one infant had persistent abnormalities at 1 year follow-up.[52]

Recurrent Kawasaki Disease

A recurrence of Kawasaki disease is defined generally as a new episode of illness meeting clinical criteria for Kawasaki disease that begins at least 3 months after the initial episode and after inflammatory markers such as the erythrocyte sedimentation rate or serum C-reactive protein level have normalized. The frequency of recurrences after first cases of Kawasaki disease in Japan was estimated to be approximately 1.9 percent during a 3-year follow-up period, with approximately 0.07 percent of patients experiencing a third episode.[250] This corresponds to a rate of 5.21 per 1000 person-years for one or more recurrences.[250] With longer follow-up, recurrence rates in Japan may approach 3 percent.[429] Data from the United States suggest a recurrence rate of 1 to 2 percent.[23] Recurrences occur most frequently within the first 2 years after the initial episode, especially in male patients and in children who have their initial episode before reaching their second birthday.[250] The frequency of recurrences in Chicago appears to be approximately 1 percent, occurring more often in Asian children, and recurrences were documented in about 2 percent of Hawaiian cases from 1996 to 2000,[132] a finding likely reflecting a racial difference. The true recurrence rate will be determined only when a specific diagnostic test becomes available for Kawasaki disease and thus minimizes recognition bias.

Family Cases

Simultaneous or sequential cases of Kawasaki disease in siblings, twins, or other family contacts also have been reported, particularly during outbreaks in Japan.[91,139,221,430] Japanese epidemiologists have documented secondary sibling cases in approximately 1 percent of cases, a rate that is approximately 10 times greater than that in the general child population.[91] However, such figures are difficult to interpret because they may be influenced by recognition and reporting biases. Sibling cases are reported to occur more frequently in twins than in nontwins. Only three sibling pairs were recognized in approximately 1900 Chicago patients, and none were reported in 400 children in Los Angeles.[219] A report from two U.S. medical centers noted 18 families with multiple affected Kawasaki disease patients, including 9 families with 2 affected siblings and 9 with Kawasaki disease in two generations or in multiple affected members.[68]

Epidemics and Outbreaks

Japanese investigators noted large nationwide outbreaks of Kawasaki disease in 1979, 1982, and 1985 to 1986, with wavelike spread occurring from one prefecture to the next, suggesting an infectious origin.[252,423,425] The 1982 Japanese epidemic started simultaneously in four areas and spread outward from each region, similar to the way that epidemic influenza spreads in Europe and America.[252,423] In the 1985 to 1986 Japanese epidemic, investigators identified epidemic "waves" that spread outward from an initial focus in the Tokyo metropolitan area and extended simultaneously northward and southward to involve most of the country within approximately 4 months.[252,423,425] A similar but less distinctive pattern of interprefectural progression in waves was noted in the 1982 Japanese epidemic. Within the northern Tohoku District, for example, Kawasaki disease spread from prefecture to prefecture over a period of approximately 7 months.[423] Korean epidemics were detected 7 and 15 months after the Japanese epidemics of 1979 and 1985 to 1986, respectively.[194,423] More localized outbreaks also have been observed. In the United States and elsewhere, community-wide outbreaks were documented beginning in 1977.[24,398] Investigation of outbreaks provides opportunities to study potential risk and etiologic factors. Clustering of cases within families, schools, or neighborhoods is quite unusual, even during large-scale epidemics. Japanese investigators have associated epidemics with a significantly increased likelihood of second cases occurring in families, fatalities, and recurrent cases, but the implications of these findings are uncertain. It is striking that since 1986 no further nationwide Japanese outbreaks have been identified, suggesting that the epidemiology of Kawasaki disease may have changed.[327,432]

Geography

Kawasaki disease has been diagnosed throughout the United States and Japan and in virtually all developed and many developing countries on all continents, including temperate and tropical zones.* No striking rural-urban differences have been noted. Elevation, longitude, and latitude have not been implicated. Travel histories of patients are unremarkable, although an anecdotal report of a 7-month-old infant in Australia documented Kawasaki disease onset 17 days after leaving Japan during that country's 1982 epidemic.[354]

Seasonality

In Japan, Kawasaki disease occurs year round but is most prevalent in the winter, with peaks usually occurring in December or January, with a lower peak in June, and the lowest number of cases in October.[36,409,426,429] In Korea, peaks were observed in summer and winter,[288] in Taiwan in summer,[138] in Beijing and Shanghai China in spring and summer,[74] and in spring in Sichuan and Hong Kong.[211,263] In the United States and other temperate areas, the number of cases peaks in the winter and early spring and is lowest in late summer; nonetheless, cases occur throughout the year.[23,25,133,219,299] No clear seasonality has been seen in Hawaii.[132] Winter predominance has been observed in at least some Southern Hemisphere countries. That sporadic cases are recognized year round

*References 32, 47, 84, 215, 294, 323, 325, 397.

is somewhat different from the pattern usually observed with highly transmissible respiratory viral diseases, incidences of which peak sharply in the winter and spring (e.g., measles, rubella, influenza).

Communicability

Although little direct evidence exists that Kawasaki disease is transmissible from person to person, considerable circumstantial evidence supports an infectious origin. Secondary or co-primary cases in families occur but are not common. Several outbreak investigations found a higher rate of antecedent respiratory tract illness in patients with Kawasaki disease compared with matched controls.[24,375] This finding is of particular interest in view of the finding that immunoglobulin A (IgA) plasma cells infiltrate the proximal respiratory tract and that viral-like inclusion bodies are observed in bronchial epithelial cells in fatal cases of Kawasaki disease, and it strongly supports a respiratory mode of spread of an inciting agent (see later).[134,318] Japanese family data suggest that sibling cases cluster either on the same day as the index case or 7 days later.[91] Because these results are based on questionnaire data, however, the possibility of ascertainment bias is great; thus, determining the degree to which Japanese familial cases represent co-primary or secondary cases is difficult.

Other Risk Factors

In addition to demographic risk factors for Kawasaki disease, specific exposures that could be related to an etiologic agent have been linked to the disorder by older epidemiologic investigations. History of more frequent recent antecedent respiratory illnesses in cases compared with controls was documented in the early 1980s.[24] Because many viral agents are prevalent in the winter and spring, when Kawasaki disease is most prevalent, some "background" isolation of various viruses from patients and from matched controls is expected.

Other past reported Kawasaki disease associations include exposure to recent carpet cleaning or shampooing, exposure to house dust mites, and residence near bodies of water; very few recent reports support these associations. The association of Kawasaki disease with exposure to recently cleaned or shampooed carpets was observed in some reports* but not in others.† The significance of a possible association with shampoo is unclear, because it is absent entirely in many well-studied outbreaks and because carpets are relatively uncommon in Japan.[62,238] Conceivably, rug shampooing could lead to aerosolization of a microbial or sensitizing agent present in the carpet, such as mites or microbial agents. A possible link between Kawasaki disease and house dust mites (chiefly *Dermatophagoides farinae* and *D. pteronyssinus*) was initially proposed as an allergic hypothesis.[105] Some investigators suggested that Kawasaki disease could result from an infectious agent in dust mites.[90] However, counts of dust mites were not significantly different in the houses of case and control patients,[114,141] and no evidence of increased anti-mite IgE, IgG, or antibodies to *D. pteronyssinus* was found in patients with Kawasaki disease.[114,149]

In a small number of outbreaks, investigators from the CDC found that patients with Kawasaki disease lived closer to "bodies of water" compared with control patients.[300,301] However, other studies, including one in Washington State, did not find living in proximity to water to be a risk factor.[64]

ETIOLOGY

The origin of Kawasaki disease remains unknown. However, clinical and epidemiologic features strongly suggest that the disease has an infectious cause. A self-limited, usually nonrecurring illness manifested by fever, rash, enanthem, conjunctival injection, swollen and red hands and feet, and cervical adenitis fits well with an infectious cause. The epidemiologic features noted earlier, including the striking age distribution (Fig. 77-1), winter-spring seasonality in most areas, occurrence of community outbreaks with wavelike geographic spread, and apparent epidemic cycles, resemble those of a transmissible disease of childhood. The laboratory features, including leukocytosis with a "left shift," elevated acute-phase reactants, and pyuria, also suggest infection. Vasculitis with inflammatory cell infiltration (including IgA plasma cells)[318] may be primarily infectious or may represent an immune reaction to infection.

A very attractive hypothesis is that Kawasaki disease is caused by a ubiquitous infectious agent that produces clinically apparent disease only in selected, genetically predisposed individuals, with particular predilection for Asians. Its rarity in the first few months of life and in older children and adults suggests an agent to which virtually all adults are immune and from which very young infants are protected to some degree by passive maternal antibody. Consistent with this hypothesis is the paucity of evidence of person-to-person spread of Kawasaki disease, because most infections are likely asymptomatic, and only very few of those infected likely develop clinical features of Kawasaki disease. This would be analogous to acute poliomyelitis, the relatively uncommon complication of poliovirus infection that occurs in only approximately 1 in 200 of those infected. However, efforts to identify an infectious agent of Kawasaki disease using conventional bacterial and viral culture and serologic methods, as well as inoculation of primates, mice, and guinea pigs, have failed to yield an infectious cause.[321,346]

Two major theories to explain the etiology of Kawasaki disease have gained prominence in the past decade: the specific respiratory pathogen theory[311] and the superantigen theory.[205] A very long list of microorganisms, including bacteria, leptospires, spirochetes, fungi, chlamydia, rickettsiae, and viruses, have been suggested at one time or another to cause Kawasaki disease, without confirmation.[321] *Yersinia*, particularly *Y. pseudotuberculosis*, causes a systemic illness resembling Kawasaki disease in selected areas of Japan,[328] but convincing evidence of an etiologic link between *Yersinia* and Kawasaki disease is lacking, despite the use of molecular tools.[378]

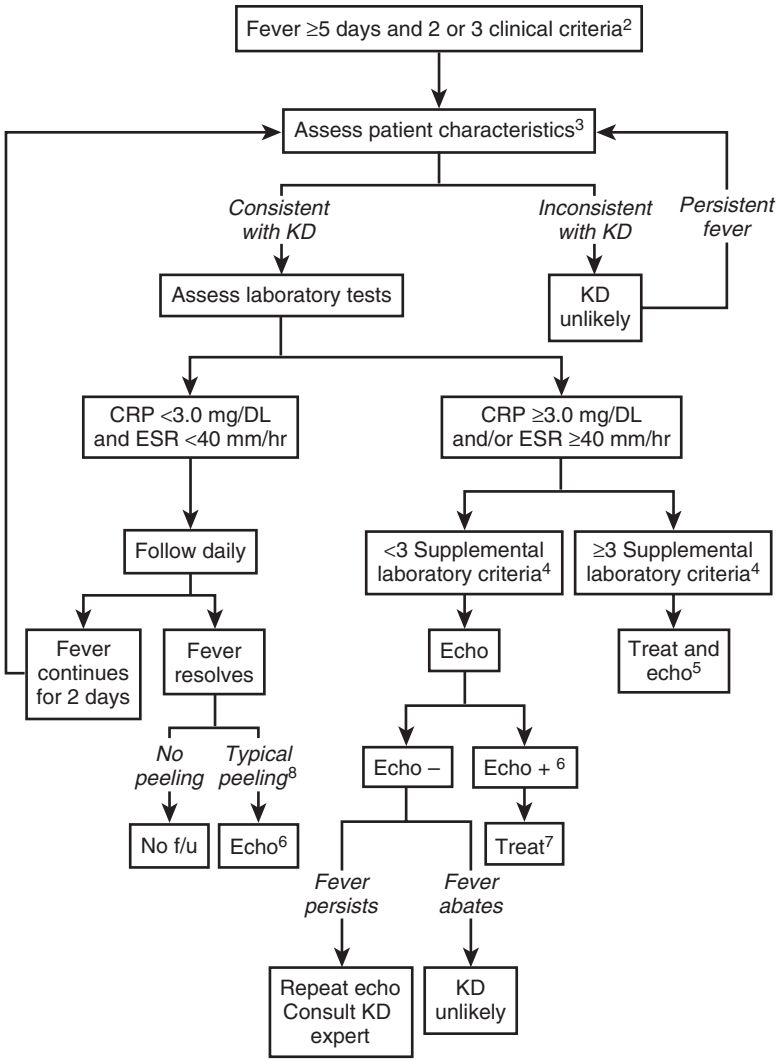

FIGURE 77-1 ■ Evaluation of suspected incomplete Kawasaki disease (KD). *1,* In the absence of a gold standard for diagnosis, this algorithm cannot be evidence based but rather represents the informed opinion of an expert committee. Consultation with an expert should be sought anytime assistance is needed. *2,* Infants up to 6 months old on day 7 or later of fever without any other explanation should undergo laboratory testing and, if evidence of systemic inflammation is found, an echocardiogram, even if the infants have no clinical criteria. *3,* Patient characteristics suggesting Kawasaki disease are listed in Table 77-1. Characteristics suggesting disease other than Kawasaki disease include exudative conjunctivitis, exudative pharyngitis, discrete intraoral lesions, bullous or vesicular rash, or generalized adenopathy. Consider alternative diagnoses (see Table 77-2). *4,* Supplemental laboratory criteria include albumin less than or equal to 3.0 g/dL, anemia for age, elevation of alanine aminotransferase value, platelet count after seventh day 450,000/mm^3 or greater, white blood cell count 15,000/mm^3 or higher, and urine specimen showing 10 or more white blood cells per high-power field. *5,* The patient can be treated before an echocardiogram is performed. *6,* Echocardiogram is considered positive for purposes of this algorithm if any of three conditions are met: Z score of left anterior descending (LAD) or right coronary artery (RCA) equal to 2.5 or greater, coronary arteries meet Japanese Ministry of Health criteria for aneurysms, or three or more other suggestive features exist, including perivascular brightness, lack of tapering, decreased left ventricular function, mitral regurgitation, pericardial effusion, or Z scores in LAD or RCA equal to 2.0 to 2.5. *7,* If the echocardiogram is positive, treatment should be given to children within 10 days of fever onset and to those beyond day 10 with clinical and laboratory signs (C-reactive protein [CRP], erythrocyte sedimentation rate [ESR]) of ongoing inflammation. *8,* Typical peeling begins under nail bed of fingers and then toes. See the text for further details. f/u, follow-up. (From Newburger JW, Takahashi M, Gerber MA, et al. Diagnosis, treatment, and long-term management of Kawasaki disease. American Heart Association Scientific Statement. *Circulation* 2004;**110**:2747–71.)

That Kawasaki disease may be caused by a novel retrovirus was suggested when two groups reported reverse transcriptase activity in cultured peripheral blood mononuclear cells from patients with acute Kawasaki disease.[37,344] Other studies failed to confirm this finding,[230,278,319] although features resembling Kawasaki disease have been described in adults with HIV infection.[148]

The hypothesis that Kawasaki disease may be related to a bacterial superantigenic toxin was suggested because of possible selective expansion of $V\beta_2$ and $V\beta_8$ T-cell receptor families among circulating mononuclear cells.[1] Superantigens such as bacterial toxins bind to major histocompatibility complex (MHC) class II molecules on monocytes and B cells and to the T-cell receptor, with resultant activation of large numbers of immunoreactive

cells with release of inflammatory cytokines. Superantigens potentially cause expansion of autoreactive T cells.[127,183] Features of immune cell activation characterize the acute phase of Kawasaki disease. Toxic shock syndrome and Kawasaki disease share the features of fever, rash, conjunctival injection, and convalescent desquamation to some degree, but differences are present, such as the rarity of hypotension in Kawasaki disease and the absence of maculopapular or erythema multiforme–like rashes in toxic shock syndrome.[121,292] Reports of selective expansion of the $V\beta_2$ and $V\beta_8$ T-cell receptor families in acute Kawasaki disease,[1,2,58] were not confirmed by others.[3,266,295,400] Although 11 of 16 patients with Kawasaki disease and only 1 of 15 controls were colonized with toxic shock syndrome toxin I (TSST-I)–producing staphylococci,[205] *Staphylococcus aureus* colonization rates, including by TSST-I–producing staphylococci, were not significantly different among patients with Kawasaki disease and controls in other studies.[206,217,392] That most studies failed to show *any* disturbance of Vβ T-cell receptor expression in Kawasaki disease substantially challenges the superantigen hypothesis.[65]

More recent investigations indicate that the immune response in Kawasaki disease is oligoclonal (antigen driven, i.e., a response to a conventional antigen) rather than polyclonal (as typical in superantigen-driven responses), with both B-cell and T-cell oligoclonality demonstrated.[51,320] In a series of studies, Rowley and colleagues[314,318] demonstrated that IgA plasma cells infiltrate peribronchial, coronary arterial, and other tissues in patients who died of Kawasaki disease in the acute stage and that the IgA plasma cells are oligoclonal,[320] findings very strongly suggesting an immune response driven by a conventional agent. Using the techniques of modern molecular biology, Rowley and colleagues[311] synthesized oligoclonal antibodies from the IgA genes from a fatal acute-stage case of Kawasaki disease and used those antibodies to identify an antigen in acute Kawasaki disease (but not control) bronchial epithelial cells and in a subset of macrophages in inflamed acute Kawasaki disease tissues, including coronary arteries. This antigen was localized to distinctive perinuclear, primarily apical, intracytoplasmic "spheroidal bodies" in acute Kawasaki disease ciliated bronchial epithelium. Light microscopic and transmission electron microscopic studies showed that the bodies are homogeneous electron-dense perinuclear inclusion bodies up to 1.4 μg in diameter that contain both protein and RNA and are consistent with aggregates of viral proteins and RNA, possibly related to the etiologic agent of Kawasaki disease.[312] Electron microscopic studies strongly suggest the presence of viral-like particles associated with the inclusion bodies, and work is ongoing to identify the particles.[313,314]

Reports of an association between a novel human coronavirus (dubbed HCoV-NH but later shown to be HCoV-NL63) in 2005[81] were not confirmed in several additional studies from four countries.[22,48,71,78,337] Efforts to associate Kawasaki disease with exposure to drugs[135] or to such environmental pollutants as toxins, pesticides, chemicals, and heavy metals have failed. However, clinical similarities between Kawasaki disease and acrodynia (mercury poisoning) are notable.[16]

Some have suggested that Kawasaki disease may be an immunologic response triggered by any of several different microbial agents. Consistent with this hypothesis is documented infection by different microorganisms in different individual cases, failure to detect a single microbiologic or environmental agent after 4 decades of study, and analogies to other multifactorial syndromes (e.g., aseptic meningitis). However, this hypothesis is difficult to reconcile with the distinctive clinical and laboratory pictures of Kawasaki disease, with its epidemiologic features such as epidemics and wavelike geographic spread, and with the studies of Rowley and colleagues in which a single monoclonal antibody reacts with almost all tissues tested from Kawasaki disease patients.[311,312]

A new hypothesis suggests that the agent of Kawasaki disease may be carried from central Asia to Japan, Hawaii, and San Diego on dust particles, based on analysis of wind patterns and Kawasaki disease time-space clustering and seasonal occurrence.[306] This awaits supporting data.

Clearly, conventional culture and serologic methodologies have failed to yield the causative agent of Kawasaki disease. In addition, establishing the diagnosis can be difficult, particularly in young infants and in those with incomplete or atypical presentations.[28,42,317] A useful diagnostic test probably cannot be developed unless it is based on the etiologic agent, and more specific therapy and preventive efforts also await discovery of the cause of this disease. The hope is that the use of modern molecular biology techniques[311,312,316,320,343] will finally clarify the origin of Kawasaki disease, as well as provide insights into the mechanisms of disease pathogenesis.

Genetic Susceptibility

The higher rates of Kawasaki disease in those of Japanese and some other Asian backgrounds suggest a genetic basis rather than environmental factors, as supported by increased rates among third- and fourth-generation immigrants from Japan to Hawaii.[132] The increased incidence of Kawasaki disease among siblings and parents of patients also supports a genetic predisposition.[410,427] The genetic basis is complex, and no single human leukocyte antigen (HLA) or MHC class II gene is common to most patients with Kawasaki disease. Immunoglobulin allotypic markers were studied as possible genetic markers for Kawasaki disease, and differences between patients and race-matched controls were found in Japanese and whites, supporting a complex genetic basis for susceptibility to Kawasaki disease.[349] Transmission disequilibrium studies involving children with Kawasaki disease and their parents demonstrated evidence of the genetic basis of susceptibility, with Onouchi and colleagues identifying functional polymorphisms in the *inositol triphosphate kinase-3 (ITPKC)* gene on chromosome 19 and in *CASP3* on chromosome 4, which confer risk in Japanese and white children.[41,279,280]

Genome-wide association studies to define Kawasaki disease susceptibility risk loci have identified additional loci on chromosome 8 and other chromosomes.[33,281,418] Davila and colleagues, also in a genome-wide association study, identified a polymorphism in the *FCGR2A* gene on chromosome 1 related to immune activation as a

Kawasaki disease risk marker.[63] Several additional loci have been identified in the Taiwanese population.[418] The picture is emerging that there are more than 6 to 10 genetic susceptibility markers for Kawasaki disease, each of which is associated with a 30 to 40 percent increased risk for Kawasaki disease compared with controls. This is an area of intense research activity.

PATHOLOGY AND PATHOGENESIS

Relationship with Infantile Periarteritis Nodosa

When the first Japanese survey of Kawasaki disease in 1970 yielded reports of 10 deaths, the pathologic diagnosis was thought to be IPAN.[145,168,182] Japanese and Western investigators quickly recognized the pathologic similarities between fatal Kawasaki disease and IPAN, long known to have an unusual predilection for the coronary arteries.[4,20,21,381-384] In the most definitive study, Landing and Larson[189,193] showed clearly that IPAN and fatal Kawasaki disease were indistinguishable pathologically. Published case reports of autopsies of children with IPAN frequently contain clinical histories that include many or all features of acute Kawasaki disease and the development of severe vasculitis affecting primarily the coronary arteries.[305] The failure of some reported patients with IPAN to meet Kawasaki disease case criteria applied retrospectively is likely related to documentation bias and to the young age of many of the patients. Young infants with Kawasaki disease are less likely to have a classic presentation than are older children (see later). When pathologic and clinical criteria are combined, the two diseases appear indistinguishable. Adult-type periarteritis nodosa was described first in 1866 by Kussmaul and Maier,[188] and it differs from IPAN primarily by the presence of hypertension and involvement of small and medium muscular arteries, especially in the lung, kidney, and intestines[92,189,383,384] An early recorded case of possible IPAN dates from 1899.[185] In 1959, Munro-Faure[242] very clearly delineated a syndrome of infantile necrotizing arteritis with coronary artery involvement, fever, rash, conjunctival and pharyngeal infection, and cervical adenitis, distinct from classic periarteritis nodosa. Roberts and Fetterman[305] and others expanded on these observations to define a distinct clinicopathologic syndrome of IPAN shortly before Kawasaki recognized the clinical syndrome.[164,165]

Coronary artery aneurysms were described as early as the early 20th century, with a male-to-female ratio of roughly 3:1, including a male preponderance in childhood cases. Childhood death from multiple coronary artery aneurysms was known to occur at least as early as 1871, as reported by Samuel Gee.[108] The cardiac specimen from Gee's case, formalin fixed for more than 120 years in the pathology museum at St. Bartholomew's Hospital, London, recently was sectioned and examined histologically. The coronary arteries showed the characteristic histologic findings of inactive Kawasaki disease and IPAN.[345] Whether these early cases with childhood coronary artery aneurysms truly represented early examples of Kawasaki disease is not certain; details of the clinical histories usually were scant.[108,298] What is clear, however, is that most of these cases greatly resemble (and very likely do, in fact, represent) Kawasaki disease.[55,83,108,242,298] From the features of many such early case reports, a reasonably accurate picture of Kawasaki disease as recognized today emerges. It is highly likely that in the decades before the introduction of the measles vaccine in the 1960s, cases of Kawasaki disease were misdiagnosed as measles, scarlet fever, drug hypersensitivity, or other common conditions.

Pathologic Features of Kawasaki Disease

Cardiac death in Kawasaki disease generally occurs in the subacute or convalescent stages of illness but also can occur earlier.[251,253] Autopsy findings usually reveal evidence of active or inactive vasculitis, which is most severe in the medium-sized arteries, with a marked predilection for the coronary arteries.* Small arterioles, larger arteries, capillaries, and veins also are affected to a lesser extent.[9,92] In more than 80 percent of fatal cases in the acute stage, the immediate cause of death is acute thrombosis of inflamed coronary arteries, with resultant myocardial infarction. In a few early deaths, pancarditis with inflammation of the atrioventricular conduction system apparently caused a fatal arrhythmia or intractable congestive heart failure, whereas small numbers of other deaths have been associated with acute coronary rupture, usually within a few weeks of the onset of illness. Deaths that occur months to years after the acute episode of Kawasaki disease often are secondary to coronary stenosis, with or without acute thrombosis, resulting in myocardial ischemia. In some patients with coronary artery abnormalities (usually in those who also have quite severe coronary disease), aneurysms of other major medium-sized arteries, including the brachial, renal, and iliac arteries, also may be present. Although phlebitis may be found, vascular inflammation more typically and more severely affects medium-sized musculoelastic arteries in their extraparenchymal portions. In the acute stage of Kawasaki disease, systemic inflammatory changes also are evident in many other organs, including myocardium, pericardium, cardiac valves, cerebrospinal fluid, lung, lymph nodes, pancreas, spleen, joints, and liver.[10,92,236]

A recent extensive study by Orenstein and associates of hearts from 32 patients who died and 8 who received heart transplants sheds new light on the pathologic features of severely affected Kawasaki disease patients.[282] Three characteristic vasculopathic processes were identified by light and transmission electron microscopy: (1) acute self-limited necrotizing arteritis (NA), (2) subacute/chronic (SA/C) vasculitis, and (3) luminal myofibroblastic proliferation (LMP). NA is a neutrophilic process that starts at the endothelial lining of vessels only in the first 2 weeks of illness, progressively destroying the vessel wall and causing development of saccular aneurysms, which can thrombose or rupture. SA/C vasculitis begins within the first 2 weeks of illness in the adventitia/perivascular

*References 8, 9, 94, 189, 374, 383, 384.

tissue and damages the vessel wall during its progression toward the lumen. This can lead to fusiform and saccular aneurysms that can thrombose, and it is associated with transition of medial and adventitial smooth muscle cells into smooth muscle cell–derived myofibroblasts which with LMP leads to stenosing luminal lesions (SA/C-LMP). LMP can also occur in some areas without local SA/C vasculitis.[313] NA is the only self-limiting of these three processes, is responsible for the earliest morbidity and mortality, and is consistent with acute viral infection. SA/C vasculitis can begin early but can persist for months or even years, whereas LMP causes progressive arterial stenosis and thrombosis and is composed of unique smooth muscle cell–derived activated myofibroblasts.

In time, the vessel wall may become stenotic, and occlusion by stenosis or by superimposed thrombus can result. Calcification of thrombi may occur,[282] and intraluminal thrombus may become organized, remodeled, and recanalized.[8,255,327,370] Several groups investigated the mechanisms of vascular remodeling in Kawasaki disease. Suzuki and colleagues[371] reported that immunohistochemistry studies indicate that active remodeling continues for at least several years after the onset of Kawasaki disease, with luxuriant intimal proliferation and neoangiogenesis. Extensive expression of vascular growth factors, including vascular endothelial growth factor (VEGF) within smooth muscle cells, was evident particularly in newly formed microvessels in the intima.[371] Gavin and colleagues[107] showed the prominence of matrix metalloproteinases in this process, particularly within the intima and media. Suzuki and associates[372] found evidence of inflammatory changes in the intact coronary artery of a child who died 13 months after having Kawasaki disease and who had no evidence of coronary artery involvement during the acute stage.

Fujiwara and associates[93,95] identified significant atrioventricular conduction system lesions in 5 of 10 autopsy specimens, with a strong correlation found between ECG findings, especially PQ-segment prolongation, and acute inflammation of the atrioventricular conduction system. Severe acute changes were most pronounced at 21 to 31 days after onset. In a unique study of right ventricular endomyocardial biopsy specimens in 201 patients with uncomplicated acute Kawasaki disease, Yutani and associates[435,436] noted some degree of myocarditis and cellular infiltration, ranging from very mild (subclinical) to quite severe myocardial inflammation, in all of the patients studied.

A histologic-immunochemical study examined the intercostal arteries to compare the nature and developmental processes of lesions with those of the coronary arteries.[220] Although similar lesions were seen, the lesions appeared somewhat later in the intercostal arteries.

The precise nature of the inflammatory infiltrate in the vessel wall or myocardium has been studied. Terai and colleagues[390] demonstrated helper (CD4) T cells and monocytes/macrophages in the arterial wall of one patient with fatal acute Kawasaki disease, as well as expression of class II MHC antigen (an activation marker) in coronary vascular endothelium, findings supporting the importance of immune responses in this form of vasculitis. Terai and colleagues[393] also reported evidence of eosinophils in epicardial microvessel lesions in acute Kawasaki disease leading to death.

Rowley and associates[316] demonstrated the presence of many plasma cells of the IgA isotype in the vascular walls of patients who died in the acute stage. They also showed that the IgA plasma cells are oligoclonal (i.e., they appear to be responding in an antigen-driven process)[320] and that they can be observed also in peribronchial, pancreatic, and renal tissues.[318] A predominance of CD8 cytotoxic/suppressor T cells over CD4 helper T cells in seven of eight acute-stage deaths also was observed in my colleagues and my laboratory by immunohistochemistry.[31] Takahashi[375] reported $CD68^+$ monocytes and macrophages to be most prominent in acute Kawasaki disease, but $CD3^+$ cells (T cells), $CD20^+$ cells (B cells), and neutrophils also were present in autopsy specimens of children who died in the first month of the illness.

Other less commonly reported pathologic findings include renal infarcts and glomerular histologic changes, possible evidence of immune complex deposition,[322] including mesangial deposition of IgM and C3, and multifocal periglomerular infiltration of lymphocytes and IgA plasma cells.[318] Changes have been noted in noncoronary arteries, the thymus, and lymph nodes. Tanaka[381] described thymic atrophy and nondiagnostic lymph node changes at autopsy (although most patients likely had been treated with corticosteroids). Naoe and colleagues[256] reported that cervical lymph node biopsy specimens showed thrombotic arteriolitis, severe lymphadenitis with necrosis, and postcapillary venules with endothelial cell and reticular cell hyperplasia. Other reports described early lymph node biopsy specimens showing multiple foci of necrosis and fibrin thrombi within the microvasculature, as well as T-zone hyperplasia, B-zone macrophage infiltration, and immunoblast proliferation.[112] Rowley and associates[318] identified IgA plasma cells not only in vascular and renal tissues but also in pancreatic and peribronchial locations. Miura and colleagues[236] found prominent macrophage infiltration of pancreatic acini and islets in 3 of 10 fatal cases.

CLINICAL MANIFESTATIONS

Clinical Phases of Illness

The clinical course of Kawasaki disease can be divided into acute, subacute, and late or convalescent phases. The *acute* febrile phase begins with fever, rash, conjunctival injection, "strawberry" tongue, red swollen lips, edema and erythema of the hands and feet, cervical lymphadenitis, and sometimes aseptic meningitis and mild hepatic dysfunction. Young children often are quite irritable. Evidence of myocarditis, rarely including congestive heart failure or arrhythmias, may develop during this time. Pericardial effusion, mitral regurgitation, or depressed myocardial function may be detected by echocardiogram. Without IVIG and aspirin treatment, the acute phase generally lasts 8 to 30 days (mean, 11 days).

After defervescence, the physical findings rapidly disappear, but during this *subacute* phase, the child may remain irritable and anorectic, with decreased activity.

Some conjunctival injection may persist. Arthritis or arthralgia, mainly of larger joints, may develop in the subacute phase. Desquamation of fingers and toes, typically beginning in the periungual region, and thrombocytosis are very common manifestations during this period. The subacute phase persists until the child has returned to his or her normal state of health at 3 to 6 weeks after the onset of fever, with normalization of inflammatory markers. The time of greatest risk for sudden death occurring from acute coronary artery thrombosis in patients with coronary lesions is during the subacute phase and the early convalescent phase. The *convalescent* phase begins when all clinical signs and symptoms have disappeared and inflammatory markers are normal, usually at 6 to 8 weeks after onset.

When manifested completely, Kawasaki disease is a distinctive clinical entity with a fairly predictable course.[59,262] The principal clinical diagnostic criteria are presented in Table 77-1. A diagnosis of typical or classic Kawasaki disease, according to these accepted clinical criteria, is made in patients with fever and at least four of the five clinical criteria and with exclusion of other illnesses that mimic Kawasaki disease. Each of the five clinical features is present in 80 to 90 percent of patients with typical cases, except cervical lymphadenopathy, which is present in approximately 50 percent of patients. However, children who do not fulfill the classic criteria for diagnosis of Kawasaki disease, in fact, may have the illness and are at risk for developing complications, particularly coronary artery disease (see section on incomplete or atypical Kawasaki disease, later).[262,317] Kawasaki disease should be considered in the differential diagnosis of infants and children with fever for at least 5 days associated with two or more of the five classic features: (1) generalized polymorphous erythematous rash, (2) conjunctival injection, (3) characteristic changes of the lips and mouth, (4) bilateral redness and swelling of the hands and feet, and (5) unilateral nonfluctuant cervical lymph node enlargement greater than 1.5 cm.[262] All features are not necessarily present at the same time. The most commonly encountered diseases to be excluded are febrile exanthems, presumably viral, including measles; acute streptococcal and staphylococcal infections; and drug hypersensitivity reactions. Japanese diagnostic guidelines for Kawasaki disease are similar to the U.S. guidelines with rare exception: they consider fever and the other five major features to be six equal criteria and require at least five of those six criteria for diagnosis.[17] Thus, a child could have no fever but all five other criteria and be considered a typical case by the Japanese criteria.[16] The Japanese criteria also accept a course of fever lasting less than 5 days if it is shortened by early IVIG treatment.[17]

Certain scoring systems using clinical and laboratory features have been developed, primarily in Japan.[14,123,254] The initial goal of these systems was to identify those patients with Kawasaki disease at highest risk for development of coronary abnormalities and who, therefore, would benefit most from receiving IVIG therapy, as well as those at low risk for coronary changes who could be spared IVIG treatment. This practice has decreased in Japan because no such scoring system appears sufficiently sensitive and specific to enable selective therapy (i.e., to allow nontreatment of patients predicted to be at low risk for development of coronary abnormalities). More recent scoring systems have focused on identifying patients at high risk for IVIG treatment failure and coronary abnormalities who may benefit from more aggressive primary therapy.[178,179] Patients who are at greatest risk are as follows: those younger than 1 year old; male patients; those with prolonged or recurrent fever; and those with anemia, hypoalbuminemia, hyponatremia, and thrombocytopenia. The Kobayashi scoring system is not effective in predicting treatment failure in multiracial populations as seen in the United States.[178,352] All patients diagnosed with Kawasaki disease within the first 10 days after onset of disease and those diagnosed later who are still manifesting significant inflammation should be treated with IVIG and aspirin.[262]

In Kawasaki disease, fever typically is high spiking and remittent, with peak temperatures generally exceeding 39° C (102.2° F) and in many cases exceeding 40° C (104° F). Unless treatment is initiated with IVIG and aspirin, fever persists for a mean of 11 days,[129] but it may continue for 3 to 4 weeks and rarely longer. In patients whose disease is treated with 80 to 100 mg/kg/day of aspirin and a single 2 g/kg dose of IVIG, fever generally resolves within 1 to 2 days.[257,261]

Bilateral painless vascular injection of the bulbar conjunctivae, clearly more severe than injection of the palpebral conjunctivae and sparing the limbic region around the cornea, generally is seen in the first week of illness, usually beginning shortly after onset of fever. It generally is not associated with exudate, conjunctival edema, or corneal ulceration, thus distinguishing the eye findings of Kawasaki disease from purulent conjunctivitis and from Stevens-Johnson syndrome. Mild acute iridocyclitis or anterior uveitis, which may be noted by slit lamp examination, resolves rapidly and only rarely is associated with photophobia or eye pain.[34,109,192,275,353] Less common ocular findings include superficial punctate keratitis, vitreous opacities, vitreous and chorioretinal inflammation, lateral rectus palsy, periorbital vasculitis, and papilledema and other optic disk changes.[11,86,143,419]

Changes of the mouth and lips consist of the following: (1) erythema, dryness, fissuring, peeling, cracking, and bleeding of the lips; (2) a strawberry tongue indistinguishable from that associated with streptococcal scarlet fever, with erythema and prominent papillae; and (3) diffuse erythema of the oropharyngeal mucosae. Oral ulcerations, pharyngeal exudates, and Koplik spots are rarely, if ever, found in Kawasaki disease and when present help to exclude the diagnosis.

Changes in the extremities are among the most distinctive features of Kawasaki disease. The hands and feet become indurated and swollen with stretched, shiny skin, sometimes with painful induration. The palms and soles become erythematous, often with an abrupt change to normal skin at the wrist and ankle. Infants and young children frequently refuse to hold objects or to bear weight. In the subacute phase, a distinctive pattern of periungual desquamation of fingers and toes may occur from 2 weeks to 2 months after onset of Kawasaki disease in 50 to 70 percent of affected patients. Beau lines, which

are transverse grooves across the nails, may appear at the nail base 1 to 2 months after a case of acute Kawasaki disease and may grow out over several months. Peripheral gangrene is a rare complication (see later).

The erythematous rash associated with Kawasaki disease may take many forms. Most common is a nonspecific, diffuse, maculopapular, primarily truncal erythematous rash. Occasionally, diffuse scarlatiniform erythroderma, urticaria, or an erythema multiforme–like rash with target lesions develops. Vesicles and bullae are not seen, although very fine pustules occur rarely. Perineal erythema and then desquamation are quite common manifestations in diapered as well as toilet-trained children in the acute stage of illness. Although rashes in Kawasaki disease tend to be most prominent on the trunk, with perineal accentuation they frequently also involve the face and extremities.

Cervical lymphadenopathy is the least common of the five principal diagnostic criteria, but it sometimes is the dominant clinical feature along with fever.[356] It usually is unilateral and confined to the anterior cervical triangle. To fulfill diagnostic criteria, the enlarged node or mass of nodes exceeds 1.5 cm, is not fluctuant, usually is not associated with erythema of the overlying skin, and is not tender or only moderately tender. Lymphadenopathy generally is benign and transient. Clinicians should be aware that children with suspected acute bacterial cervical adenitis that is unresponsive to antibiotic therapy may have Kawasaki disease. Because other features of Kawasaki disease often are present but overlooked, Kawasaki disease should be considered in such febrile children without an alternate diagnosis.[356] The ultrasound appearance of lymph nodes in Kawasaki disease has been described to be similar to that of acute Epstein-Barr virus infection and distinct from bacterial adenitis.[385] The absence of changes suggesting suppuration on imaging (e.g., ultrasonography or computed tomography [CT]) of such lesions should strengthen the suspicion of possible Kawasaki disease in this setting. Impressive cervical adenopathy in patients with Kawasaki disease generally resolves remarkably promptly after administration of appropriate therapy.

The associated features of Kawasaki disease reflect its multisystemic nature (Table 77-2). Sterile pyuria as a manifestation of urethritis, occasionally with meatitis, is found in approximately half of patients. Arthritis appearing during the first week of illness can be polyarticular or oligoarticular, including the small interphalangeal joints as well as large weight-bearing joints, with a reported prevalence of approximately 7.5 percent.[115] Arthrocentesis during this early phase yields purulent-appearing fluid, with a mean white blood cell count of 125,000 to 300,000/mm^3, normal glucose levels, and negative Gram stain and bacterial cultures. Arthritis developing after the 10th day of illness has a predilection for large weight-bearing joints, especially the knees and ankles, with a somewhat lower synovial fluid white blood cell count.[129] Gastrointestinal complaints occur in approximately one third of patients, especially in older patients; these complaints may be severe, even leading to laparotomy, and they include nausea, abdominal pain, and some diarrhea. These findings may be related to a hydropic gallbladder, pancreatitis, or appendicular vasculitis.[15,437] Obstructive jaundice and acute hydrops of the gallbladder are not uncommon findings, whereas mild to moderate elevations of serum aminotransferases occur in almost half of patients. Central nervous system involvement including aseptic meningitis occurs in almost half of patients.[66] Transient unilateral lower motor neuron facial nerve palsy occurs rarely,[296] as does sensorineural hearing loss.[176] Characteristic marked irritability is very common, especially in young infants. Reactivation of inflammation at the site of a previous bacillus Calmette-Guérin (BCG) vaccination coincident with acute Kawasaki disease is a common finding in Japan, where BCG is used widely,[351] and Terp and associates observed a child in whom both a BCG site and a purified protein derivative (PPD) test site reactivated with acute Kawasaki disease.[394] Some patients experience a flare of atopic dermatitis or psoriasis during or after experiencing acute Kawasaki disease.[30,77] Various pulmonary manifestations of Kawasaki disease, including isolated pulmonary nodules,[88] pleural effusions, acute respiratory distress syndrome,[286] and pulmonary infiltrates,[411] all of which are interesting in view of the increased numbers of IgA plasma cells found in respiratory tract tissue,[316,318] have been observed.

By far, the most important associated feature of Kawasaki disease is *cardiac involvement*. Cardiac manifestations can be prominent in acute Kawasaki disease and are the major cause of long-term morbidity and mortality. In addition to the coronary artery abnormalities that

develop in 20 to 25 percent of untreated children, pericardial effusion and myocarditis with congestive heart failure, tachycardia, gallop rhythm, nonspecific changes on the electrocardiogram, or arrhythmia may occur.[153,156,158,262] An imperfect correlation exists between clinically apparent cardiac involvement and echocardiographic evidence of coronary abnormalities, although in the pre-IVIG era, echocardiographic evidence of mitral regurgitation, impaired left ventricular function, or pericardial effusion in the acute stage was shown to be predictive of subsequent coronary abnormalities.[110] Echocardiographic evidence of perivascular brightness of coronary arteries was suggested as a criterion for early diagnosis of Kawasaki disease, but a recent report did not confirm the reliability of this finding as a useful sign of incomplete Kawasaki disease.[434] Acute Kawasaki disease may involve pericardium, myocardium, endocardium, coronary arteries, and cardiac valves. Clinical and auscultatory features may include a hyperdynamic precordium, tachycardia out of proportion for the child's age and temperature, a gallop rhythm, and a flow murmur. Some infants may manifest very low cardiac output, and ECG changes (ST-segment and T-wave changes, prolonged PR interval, and arrhythmias) may be present.

A relatively recently recognized unusual presentation of acute Kawasaki disease is hypotension or shock.[72,151] Approximately 3.5 percent of patients may require admission to an intensive care unit for suspected septic shock or toxic shock but are ultimately recognized to have features of Kawasaki disease. In the few small series of cases, females and older patients have predominated, laboratory studies reveal more dramatically elevated markers of inflammation, and patients were more refractory to therapy compared with control subjects with Kawasaki disease. Hyponatremia was reported recently in a group of these patients, suggesting a possible association with the syndrome of inappropriate secretion of antidiuretic hormone.[350]

INCOMPLETE OR ATYPICAL KAWASAKI DISEASE

A substantial subset of children have illnesses that do not completely fulfill diagnostic criteria for Kawasaki disease but that include at least 5 days of fever and one, two, or three features of the disease. Incomplete or atypical Kawasaki disease (*incomplete* is the preferred term) is associated with a substantial risk for development of coronary artery aneurysms,[28,96,209,262,317] but it can be very difficult to diagnose. Incomplete Kawasaki disease occurs most frequently in young infants, who unfortunately are at greatest risk for developing coronary disease with Kawasaki disease[42,309,317]; and fatalities have occurred. The laboratory profile of incomplete cases is similar to that of classic cases, and laboratory results can increase or decrease the likelihood of the presence of Kawasaki disease in a particular patient.[262] Echocardiographic findings in the acute stage, including perivascular brightness, coronary ectasia, decreased myocardial contractility, pericardial effusion, and mild mitral regurgitation, can support the diagnosis of Kawasaki disease. Individual manifestations of Kawasaki disease in young infants tend to be more subtle than those in older children and can be fleeting.[222,309] Kawasaki disease should be considered in the differential diagnosis of prolonged fever in infants because patients are described in whom such fevers are virtually the sole manifestation of Kawasaki disease.

A committee of the American Heart Association developed a valuable algorithm to assist in the evaluation of patients with suspected incomplete Kawasaki disease (see Fig. 77-1), with emphasis placed on clinical assessment and measurement of acute-phase reactants (C-reactive protein [CRP], erythrocyte sedimentation rate [ESR]) in patients with 5 or more days of fever and two or three features of Kawasaki disease or in infants 6 months old or younger with 7 days or more of fever without other explanation.[262] In addition to elevated ESR (≥40 mm/hr) and/or CRP (≥3.0 mg/dL), a set of six supplementary laboratory criteria that can be useful in this regard is as follows: albumin, 3.0 g/dL or less; anemia for age; increased alanine aminotransferase; platelets after day 7 of more than 450,000/mm^3; white blood cell count of 15,000/mm^3 or more; and 10 or more white blood cells/high-power field in the urine sample.[262] Hyponatremia is also useful in this regard.

Retrospective diagnosis of Kawasaki disease often is based on finding coronary abnormalities on an echocardiogram, although the clinician's goal is to identify patients with incomplete Kawasaki disease before coronary changes have occurred. The existence of these patients again emphasizes the need to identify the etiologic agent of Kawasaki disease so that a diagnostic test can be developed. When possible, patients with illnesses suggesting incomplete Kawasaki disease should be referred to physicians with considerable experience in making the diagnosis.

LABORATORY FINDINGS

A specific diagnostic test for Kawasaki disease is not available and awaits discovery of the etiologic agent of the illness (Table 77-3). The laboratory features of Kawasaki

TABLE 77-3 **Laboratory Features of Kawasaki Disease**

Leukocytosis with neutrophilia
Elevated erythrocyte sedimentation rate
Elevated C-reactive protein (and other acute-phase reactants)
Anemia
Thrombocytosis after week 1
Sterile pyuria
Hypoalbuminemia
Hyponatremia
Elevated serum levels of aminotransferases and γ-glutamyltransferase
Plasma lipid abnormalities
Cerebrospinal fluid pleocytosis
Synovial fluid pleocytosis

disease, although quite nonspecific, are nonetheless characteristic of the illness. Leukocytosis, especially with neutrophilia, is typical in the acute stage, with a predominance of immature and mature granulocytes. White blood cell counts in excess of 30,000/mm^3 occur rarely, and those in excess of 15,000/mm^3 occur in approximately 50 percent of patients. Leukopenia is unusual. Toxic granulations and Döhle bodies occasionally are seen on peripheral blood smear.[26] Anemia may develop, usually with normocytic red blood cell indices, particularly in patients with more prolonged duration of active inflammation. Severe hemolytic anemia requiring transfusions occurs but is unusual and usually is related to IVIG therapy.[54,342] Curiously, Kawasaki's first patient in 1961 (and only rare subsequent patients) manifested Coombs-positive hemolytic anemia.[164,345]

Elevation of acute-phase reactants such as ESR, CRP, and α_1-antitrypsin is nearly universal in Kawasaki disease. CRP values rise and fall much more quickly than do ESR values. Additionally, IVIG therapy per se leads to elevation of the ESR (but not CRP) for several weeks, and, thus, ESR is of little or no value in assessing the degree of inflammatory activity in IVIG-treated patients; CRP or other acute-phase reactants clearly are superior for this purpose.[13]

A very characteristic feature of the subacute phases of illness is thrombocytosis, with platelet counts ranging from 500,000 to more than 1.5 million/mm^3. Thrombocytosis rarely is present in the first week of illness, usually appears in the second week, and peaks in the third week, with a gradual return to normal by 4 to 8 weeks after onset in uncomplicated cases. The mean peak platelet count is approximately 700,000/mm^3. In one study, infants younger than 1 year old with fever without a source who had platelet counts greater than 800,000/mm^3 were 17 times more likely to be diagnosed with Kawasaki disease ultimately than were infants with platelet counts lower than 800,000/mm^3.[265] No difference exists in chromium-65–labeled autologous platelet survival between cases and controls, and little correlation exists between thrombocytosis and increased platelet aggregation. The latter situation has been detected in patients with Kawasaki disease from a few days until a year after onset.[161,420] The rare patients with thrombocytopenia in the acute stage of Kawasaki disease, most often young patients, are at increased risk for development of coronary artery disease and myocardial infarction.[267,269] The mechanism of thrombocytopenia appears to be low-grade consumptive coagulopathy.[269]

Plasma lipids are markedly perturbed in acute Kawasaki disease, with depression of plasma cholesterol, high-density lipoprotein (HDL) cholesterol, and apolipoprotein A-I (apoA-I).[44,258,326] Similar changes are observed in other conditions associated with an acute-phase response.[44] Marked appearance of serum amyloid A (SAA) protein in plasma, associated with HDL3-like lipoprotein particles, is seen acutely.[44] Cabana and colleagues[44] also showed that total cholesterol, HDL cholesterol, apoA-I, and triglyceride levels normalize over the course of several weeks and that SAA disappears from plasma. The core composition of HDL normalizes more slowly than do plasma HDL cholesterol and apoA-I levels, a finding suggesting that Kawasaki disease has a profound effect on the lipoprotein profile acutely and a more subtle sustained effect on HDL composition.

Mild to moderate elevations in serum aminotransferase levels are present in as many as 40 percent of patients, and mild hyperbilirubinemia occurs in approximately 10 percent.[39] Plasma gamma-glutamyl transpeptidase levels are elevated in most patients.[395] Hypoalbuminemia and hyponatremia are associated with more prolonged and more severe disease.[123,190,350,413] Urinalysis reveals intermittent mild to moderate sterile pyuria in approximately one third of patients, although suprapubic urine generally does not show pyuria, a finding suggesting urethritis.[67,228] In those children who undergo lumbar puncture, evidence of aseptic meningitis, with a predominance of mononuclear cells, normal glucose, and normal to mildly elevated protein levels, is a common finding.[66]

Laboratory tests, even though nonspecific, can provide diagnostic support in patients with clinical features that are suggestive, but not diagnostic, of Kawasaki disease[262] and may aid in prediction of nonresponder patients, at least in Japanese patients.[178] A moderately to markedly elevated CRP (>3.0 mg/dL) or ESR (>40 mm/hr), almost universal in Kawasaki disease, is an uncommon finding in viral exanthems and hypersensitivity reactions. Platelet counts higher than 450,000 mm^3 usually are present in patients with Kawasaki disease after the seventh day of illness. In cases of incomplete Kawasaki disease associated with coronary abnormalities, thrombocytosis and elevated ESR are very common events in the acute stage. Clinical experience suggests that Kawasaki disease is unlikely if platelet counts and a full panel of acute-phase inflammatory reactants (e.g., ESR, CRP) are normal after the seventh day of illness.

Immunologic Findings

Studies of children with acute Kawasaki disease reveal widespread immune perturbations[347] and have focused on immune activation, endothelial activation, and vascular infiltration with a variety of immune cells. Marked immune activation is present and is reflected by increased levels of many proinflammatory cytokines, including tumor necrosis factor-α (TNF-α), interferon-γ, interleukin (IL)-1, IL-2, IL-4, IL-6, IL-8, IL-10, and soluble IL-2 receptor.* Increased chemokine and selectin activity also has been reported in acute Kawasaki disease.[380,416] The most intense immune activation and cytokine production occur during the acute and early subacute phases, the period of most intense vascular inflammation and of aneurysm formation. The immune perturbations subside as the illness resolves either spontaneously[201] or more promptly in response to anti-inflammatory therapy, and the benefit of therapy appears to result from immune modulating effects, although precise details are lacking.[198,340]

In acute Kawasaki disease, serum IgG levels are lower than normal for age,[261] whereas in the subacute stage, polyclonal elevation of all immunoglobulin classes is often found.[208] Serum IgE and IgM levels particularly are frequently elevated.[184,186] The increase in serum

*References 18, 76, 99, 131, 172, 191,212, 213, 224, 225.

immunoglobulins is associated with a very high proportion of circulating activated B cells,[173] which is reversed by aspirin/IVIG treatment.[200] Shingadia and colleagues[339] found decreased numbers of circulating B lymphocytes and plasma cells with surface or cytoplasmic IgA in the acute and subacute stages of Kawasaki disease, thus complementing the finding of IgA plasma cell infiltration in tissues.[316,318]

Circulating immune complexes can be detected in the subacute and convalescent (but not acute) stages; they appear unrelated to the development of coronary abnormalities by virtue of their time course of detection* and to be unaffected by IVGG infusions.[218] Some investigators have detected IgA in these immune complexes.[276] Most circulating IgG immune complexes in Kawasaki disease contain IgG1 and IgG3,[210] with Fc portions that bind to monocytes and platelets. Immune complexes in Kawasaki disease may promote aggregation of platelets, with release of vasoactive factors.[210]

Several autoantibodies have been found in Kawasaki disease sera, but antinuclear antibody and rheumatoid factor are very uncommon findings. Antibodies to type III collagen have been detected,[177] but without clear relation to coronary complications. Some acute-phase sera contain IgM antimyosin antibodies directed against epitopes that differ from those reactive with acute rheumatic fever sera, a finding suggesting a possible relationship with myocarditis in Kawasaki disease.[57] Both IgM and IgG antineutrophil cytoplasmic antibodies (ANCAs)[303,330,355] and antimyeloperoxidase antibodies[303] have been reported in Kawasaki disease. Several reports have noted IgM or IgG antiendothelial cell antibodies, which may injure endothelial cells directly or participate in complement-mediated injury or in antibody-mediated cytotoxic reactions.[152,199,202-204] Among the endothelial cell antigens of interest are adhesion molecules such as intercellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1), E-selectin, P-selectin, and endothelin, all of which may be upregulated in Kawasaki disease.[38,98,171,240,272] The precise role of immunologic reactions to endothelial cells in the pathogenesis of Kawasaki disease is unclear; Miura and colleagues[237] found focal but not widespread expression of VCAM-1 or E-selectin on endothelial cells of acute Kawasaki disease coronary arteries, especially in areas of neovascularization. However, the temporal correlation of immune activation and endothelial cell activation with secretion of monocyte chemoattractant protein-1 (MCP-1)[38,204,390] and the development of coronary abnormalities and their suppression by IVIG are consistent with an immune stimulant that triggers an immune response leading to vascular damage in part through cytokine-induced exposure of endothelial epitopes, inflammatory cell infiltration, myointimal proliferation, matrix metalloproteinase release, and other mechanisms resulting in vascular wall damage.[107,333] An animal model of Kawasaki disease induced by injected cell wall fragments of *Lactobacillus casei* has been reported and is used, but its relevance to Kawasaki disease is unclear.[197] Schulte and coworkers presented data that macrophages and dendritic cells (innate immunity) collaborate with T cells but not B cells (adaptive immunity) to result in coronary arteritis in this model.[332]

Investigation of the distribution of circulating T cells in acute and subacute Kawasaki disease has yielded conflicting results that range from no significant change in distribution of CD3, CD4, CD8, and CD19 cells at any stage of illness[51] to significant decreases in circulating CD8[207,391] or CD4[391] numbers acutely. An immunohistochemistry study of eight autopsied acute-stage Kawasaki hearts found activated T cells, a predominance of CD8 cells and macrophages, but no B cells,[31] whereas Terai and colleagues' autopsy study on a child showed predominance of activated CD4 cells and macrophages with activated coronary endothelial cells.[390] The presence of activated T cells in peripheral blood in acute Kawasaki disease is controversial. Jia and colleagues reported that Th17 helper cells and expression levels of IL-17A, IL-6, and IL-23 were significantly upregulated in children with acute Kawasaki disease whereas regulatory T cells and the transcription factor FoxP3 were significantly downregulated. These changes were more dramatic in IVIG-resistant patients.[146]

Although expansion of Vβ2 and Vβ8 T-cell receptor families in the acute stage of Kawasaki disease was reported,[1,2,58] this has not been reproduced by other investigators.* Such expansion suggests the possible role of a superantigen or could reflect clonal expansion of certain Vβ families in response to a conventional antigen. However, clonal expansion of CD8 T cells in acute Kawasaki disease supports the hypothesis that a conventional antigen rather than a superantigen is involved in the pathogenesis,[51,346] and compelling evidence of an oligoclonal IgA response in the vascular wall also strongly supports this hypothesis.[320]

Evidence for activation of neutrophils in Kawasaki disease is of interest because they, with monocytes and macrophages, are postulated to mediate endothelial cell damage by production of oxygen radicals.[268,375,407] Widespread activation of monocytes and macrophages,[100-102] T lymphocytes,[103,329] and B lymphocytes is also present.[173] Jejunal mucosal changes similar to delayed-type hypersensitivity in the epithelium and lamina propria, including decreases in $CD8^+$ cells and increases in $CD4^+$ and $HLA\text{-}DR^+$ cells, have been detected.[248] Delayed hypersensitivity skin test responsiveness to *Candida*, streptokinase/streptodornase, phytohemagglutinin, and PPD (tuberculin) is suppressed during the acute stage of Kawasaki disease but normalizes within 1 to 2 months.[431] Acute Kawasaki disease is associated with inflammatory reactivation of previous BCG vaccination sites, apparently reflecting both cellular and humoral responses.[433] Terp and colleagues cared for a patient with acute Kawasaki disease and reactivation of both a BCG site and the site of a recent tuberculin skin test.[394] Plasma fibronectin levels are reported to be decreased early in illness but to rebound to high levels by the fourth week of illness.[338]

Circulating complement components C3 and C4 commonly are elevated, probably as acute reactants in the first several weeks of illness, and then normalize.[304]

*References 128, 208, 210, 218, 276, 283, 324, 414.

*References 3, 217, 231, 266, 295, 392, 400.

Nonetheless, complement appears to be activated through the classical pathway,[180] with high plasma C4D levels.[246]

Production of the chemoattractant leukotriene B_4 by polymorphonuclear cells is increased from 13 to 29 days after onset of Kawasaki disease,[120] and it may attract more inflammatory cells to the site. Leukotriene E_4 and prostaglandin E_2 also are elevated in Kawasaki disease,[97,196,226] as are increased platelet synthesis of thromboxane A_2 and plasma levels of thromboxane B_2.[130]

The strongest evidence of the importance of immunologic factors in the pathogenesis of vasculitis in Kawasaki disease is provided by the remarkably beneficial effect of IVIG on the acute febrile illness and the marked reduction in development of coronary aneurysms.[247,257,261,273,340] This correlates with the effect of IVIG to reduce B-cell activation, more rapidly normalize T-cell activity, downregulate cytokine secretion, and induce disappearance of endothelial cell activation antigens.[198,204] Potential mechanisms of the beneficial action of IVIG in Kawasaki disease include modulation of cytokine production, suppression of endothelial cell activation, inhibition of immunoglobulin production by a negative feedback mechanism, specific neutralization of an unknown etiologic agent or toxin, nonspecific blockade of a receptor for immune complexes, and augmentation of T-cell suppressor activity.[340]

TABLE 77-4 **Treatment of Kawasaki Disease**

Acute and Subacute Stages
IVIG 2 g/kg infusion over 10 to 12 hours
Plus
Aspirin 80 to 100 mg/kg/day in four divided doses (until 14th illness day *and* patient afebrile at least 3 to 4 days), then 3 to 5 mg/kg once daily for 6 to 8 weeks.
IVIG may be repeated if fever persists or recurs together with at least one classic sign of Kawasaki disease and/or elevated C-reactive protein level (see text for other alternative "rescue therapies")
Convalescent Stage
No coronary abnormalities: no therapy
Transient coronary abnormalities: aspirin 3 to 5 mg/kg once daily at least until resolution of coronary abnormalities
Persistent small to medium coronary aneurysms: aspirin 3 to 5 mg/kg once daily
Giant or multiple small coronary aneurysms: aspirin 3 to 5 mg/kg once daily, with or without clopidogrel 1 mg/kg/day, with warfarin or low-molecular-weight heparin for most patients
Coronary obstruction: thrombolytic therapy, surgical or interventional procedures

IVIG, intravenous immunoglobulin.

MANAGEMENT

Treatment During the Acute Stage

Patients diagnosed with Kawasaki disease should be admitted to hospital, undergo a baseline echocardiogram, and receive IVIG 2 g/kg over the course of 10 to 12 hours, with high-dose aspirin at 80 to 100 mg/kg/day in four divided doses as soon as practical (Table 77-4).[59,262] When administered by the 10th illness day (onset of fever defines first day) this regimen is highly effective in reducing the risk for development of coronary abnormalities.[257] Because few data exist regarding management of patients treated later than the 10th illness day, the goal is to treat by illness day 10 whenever possible. Patients who are diagnosed after the 10th illness day and who are still febrile may benefit from therapy, but the ability to prevent coronary changes is less certain. IVIG and aspirin have been shown to prevent the development of giant coronary aneurysms[53,315] and to have direct benefits on cardiac function.[259] The mechanism of action of IVIG in Kawasaki disease remains unknown. The single high-dose schedule is superior to the earlier regimen of 400 mg/kg/day IVIG for 4 days with high-dose aspirin with respect to rapidity of defervescence and normalization of acute-phase reactants, as well as in preventing development of coronary artery abnormalities.[257,261,262,273] The large single-dose infusion generally is well tolerated, even in patients with decreased myocardial function.[259] Patients should generally remain hospitalized until they have been afebrile for at least 24 hours, to ensure that they are available for re-treatment if necessary.

Whether treatment with IVIG and aspirin earlier than the fifth illness day leads to better or poorer outcomes remains unclear. Tse and colleagues[402] compared 89 children treated on or before the fifth day of illness to control subjects treated on illness day 6 to 9.[402] These investigators found significantly fewer patients with coronary ectasia at 1 year after Kawasaki disease and shorter total fever duration in the former group, without differences in frequency of recrudescence, need for additional therapy, need for corticosteroids, length of hospitalization, or development of coronary aneurysms within 3 months.[402] Zhang and associates also concluded that patients treated before the sixth illness day had a significantly lower risk for developing cardiac sequelae compared with patients treated later than the sixth day.[438] In contrast, Muta and colleagues evaluated 4731 patients treated on illness days 1 to 4 and 4020 treated on days 5 to 9 and found that patients treated earlier were somewhat more likely to require additional therapy (odds ratio = 1.12; 95% confidence interval [CI], 1.10 to 1.16); no significant differences in cardiac sequelae were found between groups.[243] Another study also found that treatment before illness day 5 was associated with increased need for re-treatment but no difference in coronary outcome.[87]

Single infusions of IVIG at doses less than 2 g/kg have not been demonstrated to be as effective as 2 g/kg.[19,80] Terai comprehensive meta-analysis of all Japanese and North American IVIG treatment trials showed that the coronary artery outcome is correlated directly with the *total* dose per kilogram of IVIG, with 2 g/kg superior to 1.6 g/kg, which is superior to 1.2 and 1.0 g/kg; the initial dose of aspirin did not appear to influence coronary outcome.[389] Another study confirmed this finding.[75]

Patients diagnosed after the 10th illness day who are still febrile and/or who manifest other signs of active disease may benefit from IVIG and aspirin therapy because this treatment may result in prompt clinical improvement, with subsidence of fever and other signs of

inflammation. Little evidence supports that this approach results in lower rates of development of coronary abnormalities, however. Patients beyond the 10th to 12th illness day who have become afebrile and have resolved their clinical features of Kawasaki disease without therapy are unlikely to benefit from IVIG. Such children should be treated instead with low doses of aspirin, 3 to 5 mg/kg once daily, and should be evaluated carefully by serial echocardiograms. In patients who have already developed coronary aneurysms and whose acute manifestations of illness have resolved, there is no convincing evidence of a beneficial effect of IVIG.

Various preparations of IVIG differ in manufacturing processes and, therefore, in composition (e.g., the proportion of IgG monomers and the presence of proteins other than IgG). Although adverse reaction rates differ among products, clinical efficacy does not seem to differ.[310] An exception is a report that showed IVIG prepared with β-propiolactone, which can affect the biologic activity of the Fc portion of IgG, to be less effective in Kawasaki disease.[401] Immunization with live virus vaccines such as for measles and varicella should be deferred for 9 to 11 months after administration of high-dose IVIG because of impaired immune responses.

The aspirin dosage for acute Kawasaki disease that is most thoroughly studied in the United States is 80 to 100 mg/kg/day in four divided doses. I recommend that this therapy be maintained until approximately the 14th day of illness (longer if necessary to ensure that the patient has been afebrile for at least 3 to 4 days) and then reduced to a daily dose of 3 to 5 mg/kg for antiplatelet activity. The lower dose should be continued until 2 to 3 months after onset of illness in those who have not developed coronary abnormalities.[262] Patients who develop coronary abnormalities should continue to take low-dose aspirin. High-dose aspirin is used for its anti-inflammatory activity, whereas the much lower dose inhibits platelet aggregation. Japanese clinicians generally use an intermediate anti-inflammatory dose of 30 to 50 mg/kg/day because of perceived higher rates of untoward effects in Japan.[17,187] Difficulty in achieving standard therapeutic anti-inflammatory serum salicylate levels during the acute phase of illness (20 to 25 mg/dL) occasionally may complicate aspirin treatment, and selected patients with rare refractory disease may require salicylate doses in excess of 100 mg/kg/day to achieve anti-inflammatory benefit.[144] This probably reflects impaired absorption and bioavailability and enhanced salicylate clearance in acute Kawasaki disease.[181] An important note is that patients with Kawasaki disease who are receiving very high aspirin doses can suddenly increase their salicylate absorption with clinical improvement and then are at risk for toxicity. Serum salicylate levels should be monitored if symptoms of vomiting, hyperpnea, tinnitus, lethargy, or striking liver function abnormalities develop in children receiving aspirin.

A study that randomized U.S. patients to receive salicylates at 80 to 100 mg/kg/day or at 3 to 5 mg/kg/day for initial therapy (each regimen with 2 g/kg of IVIG) concluded that no difference in coronary outcome occurred, but a more prompt clinical anti-inflammatory benefit was noted in the high-dose aspirin group.[232] In the absence of IVIG, aspirin therapy does not decrease the frequency of coronary abnormalities.[75] Reye syndrome has been reported rarely in children taking high-dose aspirin for Kawasaki disease, but there are few data to suggest that low-dose aspirin poses this risk.[377]

The potential value of adding corticosteroid therapy to IVIG or aspirin for primary therapy has been addressed in several trials.[179,260,271,302] For example, Jibiki and colleagues compared 3 days of intravenous dexamethasone 0.3 mg/kg/day plus heparin and IVIG, with subsequent low-dose aspirin, to IVIG plus higher-dose aspirin and found more prompt decreases in fever and inflammatory markers in the dexamethasone-treated group but no difference in rates of coronary abnormalities.[147] Okada and associates showed that the addition of intravenous prednisolone to IVIG and aspirin followed by a long taper of oral prednisolone was associated with shorter duration of fever and more prompt fall in CRP and circulating IL-2, IL-6, IL-8, and IL-10 levels.[277] Inoue and colleagues[140] compared 88 patients treated with IVIG and aspirin to 90 patients who received in addition intravenous prednisolone 2 mg/kg/day in three divided doses until afebrile and then orally until the CRP value normalized, with a subsequent taper over 15 days, for a median of 23 days of corticosteroids. The results indicated fewer coronary abnormalities, shorter durations of fever, more rapid decline in CRP level, and fewer initial treatment failures in the steroid recipients. Caution must be exercised in the interpretation of the findings of these Japanese trials because the IVIG regimens and aspirin doses usually differ from those used in the United States and echocardiograms were not interpreted by investigators blinded to the treatment group. A well-designed U.S. trial in this regard showed little if any direct benefit of the addition of a single dose of intravenous methylprednisolone 30 mg/kg to the current IVIG and aspirin regimen, with the possible exception of the subset of patients who failed to respond to standard therapy and who required re-treatment of the disease.[260]

A recent Japanese multicenter, randomized, open-label, blinded end points trial (the RAISE study) assessed the benefit of adjunctive corticosteroid primary therapy for Kawasaki disease patients considered at high risk to be refractory to initial therapy.[179] Using the Kobayashi score[178] to identify patients at high risk for nonresponse to IVIG and aspirin, high-risk subjects were randomized to IVIG and aspirin (30 mg/kg/d until afebrile, then 3-5 mg/kg) or to IVIG, aspirin, and intravenous prednisolone 2 mg/kg/d for 5 days, converting to oral dosage once free of fever and then a 15-day corticosteroid taper beginning when the CRP level normalized. Significantly fewer recipients of corticosteroids developed coronary changes (3% vs. 13% at 4 weeks), and coronary z-scores were significantly lower in corticosteroid recipients. In another recent Japanese study,[271] Ogata and colleagues evaluated corticosteroids with IVIG and aspirin 30 to 50 mg/kg/day in those patients with disease predicted to be refractory. Subjects were randomized to IVIG and aspirin alone or with a single 30 mg/kg dose of intravenously administered methylprednisolone and heparin from 2 hours before to 24 hours after the corticosteroid was given. Corticosteroid recipients had more rapid defervescence and decline in CRP levels with somewhat lower mean coronary z-scores ($z \geq 2.5$ in 9% of

corticosteroid group, 38.5% in the noncorticosteroid group, $p = .04$), with transient adverse events only in the corticosteroid group.

Unfortunately the Japanese scoring systems to identify high-risk patients are not useful in ethnically diverse populations as seen in the United States,[352,399] and it is thus difficult to know how to target adjunctive therapy outside Japan.

Prediction of Treatment Failures

Several attempts have been made in Japan to develop scoring systems to predict, at the time of initial presentation, those patients who are at increased risk for failure to respond to standard therapy[79,178] and/or to develop coronary lesions after therapy.[239] In a retrospective analysis of 193 patients, Mori and colleagues found elevated white blood cell and neutrophil counts and CRP levels after IVIG treatment predicted increased risk for subsequent development of coronary lesions.[239] Egami and associates compared 279 patients who responded to initial standard treatment to 41 patients who were treatment resistant.[79] With their scoring system giving one point each for age younger than 6 months, treatment before 4 days of illness, platelet count less than or equal to 300,000/mm^3, and CRP 8 mg/dL or higher and two points for alanine aminotransferase level 80 IU/L or higher, a total score of three points or higher identified the IVIG-resistant group with 78 percent sensitivity and 76 percent specificity.[79] A similar predictive scoring system for IVIG unresponsiveness was developed by Kobayashi and colleagues,[178] who gave two points each for initial treatment on illness day 1 to 4, serum sodium level less than 133 mmol/L, aspartate aminotransferase value 100 IU/L or higher, and neutrophils 80 percent or greater and two points each for CRP 10 mg/dL or higher, platelet count up to 300,000/mm^3, and age 12 months or younger; this yielded 86 percent sensitivity and 67 to 68 percent specificity for patients with four or more points. The Kobayashi score was used to select patients at high risk for treatment failure in a randomized corticosteroid trial, as discussed earlier.[179]

Rescue Therapy for Treatment Failures

Most patients with acute Kawasaki disease respond promptly to treatment with IVIG and aspirin, with defervescence and subsidence of inflammatory manifestations occurring within 48 hours.[257,262,341] A subgroup of 10 to 20 percent, however, fails to show significant clinical response; these patients remain febrile 36 to 48 hours after receiving IVIG or they manifest only transient improvement, with recurrent fever and clinical evidence of inflammatory signs. These patients need additional anti-inflammatory therapy, and specific guidelines or controlled treatment trials do not exist. Of course, when treating apparently treatment-refractory patients, it is also prudent to reconfirm the initial diagnosis of Kawasaki disease.

In these patients, administration of a second dose of 2 g/kg of IVIG generally is effective in suppressing disease activity.[89,262,366] In a retrospective study of 179 patients with Kawasaki disease, 89 percent responded to the first dose of IVIG and 67 percent of the nonresponders responded to a second IVIG dose; thus, only 3 to 4 percent of all patients failed to respond after a second dose of IVIG.[122] Some recommend a course (usually 3 days) of intravenous pulse methylprednisolone at 30 mg/kg/day instead of a second dose of IVIG.[417] I generally prefer to reserve pulse corticosteroid therapy for the rare patient with highly refractory acute disease who has failed to respond to at least two 2-g/kg doses of IVIG, because early Japanese data suggested that corticosteroids may predispose to development of coronary disease and because most patients respond well to a second IVIG dose.[122,161,235] In addition, a more recent study noted coronary dilation in three of nine treatment-refractory patients shortly after pulse corticosteroids were administered.[126] No randomized comparison between repeat IVIG dosing and corticosteroids for refractory patients has been performed. In a few particularly treatment-refractory patients, I have employed a slow oral corticosteroid taper over the course of several months once inflammatory activity appeared to have been controlled.

Infliximab (Remicade), a monoclonal anti–TNF-α antibody, has been reported in an open-label experience to be effective in most patients with acute Kawasaki disease who are refractory to standard therapy[40,223]; this agent is being studied in a randomized trial of patients with refractory Kawasaki disease. Even less published experience exists regarding other therapies for IVIG-refractory Kawasaki disease. Cyclophosphamide with or without methotrexate has been used in a very small number of patients, as has plasmapheresis or plasma exchange.[412] Cyclosporine has been reported to be promising in this regard,[373] as has single-dose methotrexate.[170]

Sequelae

The major (and virtually the only) sequelae of Kawasaki disease are cardiovascular, particularly coronary artery abnormalities. Therefore, appropriate cardiac imaging is critical for the evaluation of patients suspected to have acute Kawasaki disease and for their subsequent follow-up. Echocardiography has been considered the ideal imaging modality because it is noninvasive and has high sensitivity and specificity for detection of abnormalities of the proximal left main, left anterior descending, circumflex, and right coronary arteries.[262] This procedure should be performed under the supervision of an echocardiographer experienced with evaluating children, and internal arterial diameters should be measured and compared with normal standards for body surface area, expressed as z-scores.[69,216,262] The American Heart Association classifies coronary aneurysms as small (<5 mm), medium (5 to 8 mm), or giant (>8 mm); and de Zorzi and colleagues[69] and more recently Manlhiot and coworkers[216] showed that adjusting coronary dimensions for body surface area may identify more accurately those patients with enlarged coronary arteries. Giant coronary aneurysms, defined as having 8 mm or larger internal diameter, are associated with worse prognosis, and these patients require particularly close follow-up.[53,262] The sensitivity and specificity

of echocardiography to identify coronary thrombi and coronary stenosis are uncertain, and visualization of coronary vessels is more difficult as body size increases. Therefore, angiography, magnetic resonance angiography (MRA),[117,379] and ultrafast CT angiography (CTA)[45,291] have been useful for selected patients with Kawasaki disease.[262,334]

Management Beyond the Acute Stage

Patients with Kawasaki disease should be reevaluated within 2 weeks after hospital discharge and again 6 to 8 weeks after onset of illness because echocardiography at these time points is most likely to detect coronary artery aneurysms should they develop. If a baseline study and these two follow-up echocardiograms fail to detect evidence of coronary abnormality, performing further echocardiograms probably is unnecessary,[406] although a 6- to 12-month follow-up echocardiogram is performed at many centers.[60,262] Low-dose aspirin therapy (3 to 5 mg/kg/day) can be discontinued after the 6- to 8-week follow-up echocardiogram unless evidence of coronary abnormalities is present. To reduce the theoretical (and extremely low) risk for Reye syndrome in patients receiving low-dose aspirin, clopidogrel 1 mg/kg/day can be substituted for aspirin for a brief time in patients who develop varicella or influenza. Clopidogrel also can be used in the rare patient who is allergic to, or intolerant of, aspirin.

COMPLICATIONS

Myocardial Infarction

Myocardial infarction is the most common cause of death in Kawasaki disease (Table 77-5). In a cooperative Japanese study of 195 cases, the first myocardial infarction usually occurred in the first year after onset of disease and was fatal in 22 percent and asymptomatic in 37 percent of these patients. Major symptoms were shock, vomiting, and abdominal pain, with chest pain complaints only in children older than 4 years of age. Of those patients who survived a first infarct, 16 percent had a second myocardial infarct.[155,157] Patients with giant (>8 mm or z-score >10) coronary aneurysms are at greatest risk for having infarcts, particularly related to thrombi and/or to stenotic areas adjacent to a giant aneurysm. Most fatal infarctions are the result of obstruction of the left main coronary artery or both the right coronary and left anterior descending coronary arteries; survivors are most likely to have isolated right coronary involvement. Approximately half the survivors of acute myocardial infarction had one or more complications, including ventricular dysfunction, mitral regurgitation, and arrhythmias. Parents of all children with Kawasaki disease with significant coronary abnormalities should be instructed to seek emergency medical care if chest pain, dyspnea, lethargy, or syncope develops. Prompt fibrinolytic therapy should be attempted at a tertiary care center if acute coronary thrombosis is diagnosed.[154,262] The degree of reversibility of coronary thrombosis in children with Kawasaki disease may be somewhat less than that in adults with atherosclerotic disease. Late cardiac sequelae of Kawasaki disease may not manifest until adulthood.[160] A recent Japanese study assessed long-term outcomes of 60 Kawasaki disease patients who had a myocardial infarct between 1976 and 2007, with median follow-up of 16 years. The 30-year survival rate was 63 percent (95% CI, 45% to 78%) and the 25-year ventricular tachycardia-free survival rate was 29 percent (CI, 15% to 46%). Development of ventricular tachycardia was related to degree of nonviable myocardium.[403]

TABLE 77-5 Cardiac Abnormalities in Kawasaki Disease

Acute Stage
Pericardial effusion
Decreased myocardial function
Mitral regurgitation
Brightness of coronary artery wall (controversial)
Enlargement (ectasia) of coronary arteries
Arrhythmia (rare)
Subacute Stage
Coronary aneurysms, irregularity, ectasia
Significant mitral or aortic regurgitation, or both (rare)
Coronary aneurysm rupture (very rare)
Myocardial infarction (rare)
Convalescent Stage
Persistent coronary aneurysms
Regressed coronary aneurysms (residual fibrosis)
Coronary artery stenosis
Coronary aneurysm rupture (very rare)
Myocardial infarction (rare)

Other Cardiovascular Complications

Other cardiac complications include myocardial fibrosis, valvulitis, and coronary rupture. Some researchers have suggested that valvular disease occurs in as many as 1 percent of patients with Kawasaki disease; most of these cases result in mitral regurgitation.[5,175] Patients with well-documented aortic regurgitation also have been observed. At least one patient with Kawasaki disease developed severe aortic and mitral regurgitation that necessitated double valve replacement.[111] In an autopsy study, coronary rupture was a rare finding but was noted more often among older children who died of Kawasaki disease within the first months after disease onset, whereas myocardial infarction was seen more often in younger fatal cases.[318]

Peripheral artery aneurysms develop in fewer than 1 percent of patients with Kawasaki disease, virtually always in those who also have significant coronary abnormalities.[162,369] These abnormalities generally involve medium-sized muscular arteries, such as subclavian, brachial, axillary, iliac, or femoral arteries and occasionally the hepatic or renal arteries or the abdominal aorta. In patients with Kawasaki disease who are undergoing their

first coronary arteriography, abdominal aortography and subclavian arteriography are therefore recommended.[262]

Peripheral Gangrene

A rare but very serious complication in the acute febrile stage of Kawasaki disease is severe peripheral ischemia and dry gangrene of distal extremities.[396] Virtually all such patients have been young infants up to approximately 7 months of age with giant coronary aneurysms, and some have developed peripheral (especially axillary or iliac) arterial aneurysms as well. This complication is virtually unknown in Japan[166] and has been reported primarily in non-Asian children in North America.[73,396] Possible pathogenic mechanisms of peripheral gangrene include the following: severe arteritis of digital or other small peripheral arteries; arteriospasm of peripheral arteries, perhaps in association with severe vasculitis; thrombosis of inflamed or spastic arteries as a result of stasis and damaged endothelium; thrombosis of a more proximal aneurysm (especially axillary) with embolism distally; rarely, cardiogenic shock; and, most likely, a combination of these factors.[373,388] This process has led to amputations in a small number of infants. Therapy has been empirical, primarily because the precise mechanisms of disease are unclear, and has included aggressive use of anti-inflammatory agents, prostaglandin infusion, and antiplatelet, anticoagulant, and vasodilation therapies.[73,396,415]

Nonvascular Complications

As many as 5 to 10 percent of patients with Kawasaki disease develop painful arthritis or arthralgia in the acute stage of disease, often in the ankles or other lower extremity joints, and they may benefit from treatment with a nonsteroidal anti-inflammatory agent. Earlier-onset arthritis (≤10 days of illness) tends to be polyarticular, whereas later-onset arthritis involves primarily larger weight-bearing joints. I have used naproxen, usually 10 to 15 mg/kg/day divided into two or three doses, for several weeks with considerable success.

Abdominal pain and diarrhea in the early acute stage usually respond to intravenous hydration and supportive care. Acalculous distention (hydrops) of the gallbladder manifests clinically as right upper quadrant tenderness or a mass with or without obstructive jaundice and can be confirmed by ultrasonography.[262,359] Performing a cholecystectomy is not necessary. Hepatic involvement appears to be entirely self-limited and has not been associated with chronic liver disease.

Rare patients with Kawasaki disease develop hemophagocytic syndrome, also known as *macrophage activation syndrome*, as a complication.[56,241,287] This syndrome manifests as persistent fever associated with cytopenias, hepatosplenomegaly, hepatic dysfunction, often hyperferritinemia, elevated serum lactate dehydrogenase, hypofibrinogenemia, and hypertriglyceridemia. Therapy with high doses of prednisone or other immune modifiers is indicated for this rare but serious complication.

Rare events that occur in association with Kawasaki disease include sensorineural hearing loss,[176] transient unilateral facial nerve palsy,[106,296] and pneumonitis or pulmonary nodules.[88] I have cared for two older children who had sufficient abdominal findings to warrant performing appendectomies before establishing the diagnosis of Kawasaki disease. Consultation with a center that treats large numbers of patients with Kawasaki disease should be sought by the physician faced with patients with rare or serious complications.

LONG-TERM FOLLOW-UP AND PROGNOSIS

Kawasaki disease normally is an acute and self-limited illness. However, cardiac abnormalities that develop when the disease is active may be progressive, and prognosis clearly is related to the coronary artery status. Twenty to 25 percent of patients not treated with IVIG develop coronary abnormalities that are detectable by two-dimensional echocardiography or angiography. The risk for development of coronary aneurysms is reduced to 2 to 3 percent overall when IVIG is given in the first 10 days of illness.[257,261] However, the rates for coronary abnormalities for young infants are somewhat higher, even with timely IVIG therapy. Patients who develop moderate to severe coronary abnormalities are at risk for myocardial ischemia, myocardial infarction, and even sudden death for many years after onset of illness and into adulthood.[157,227]

Children without apparent cardiac sequelae during the first month after onset of Kawasaki disease appear to return to their previous states of health without cardiac signs or symptoms. However, some reports suggest the possibility of generalized endothelial dysfunction in patients with Kawasaki disease who never had coronary abnormalities. These dysfunctions include altered lipid metabolism,[44] increased brachial-radial artery mean pulse wave velocity,[50] lower myocardial flow reserve,[245] and abnormal endothelium-dependent brachial artery reactivity,[70,234,264,421] but the data conflict somewhat, and additional studies are needed.

Regression of small and medium aneurysms as seen on an echocardiogram is a common occurrence. Overall, approximately half of all children with coronary aneurysms at 4 to 8 weeks after onset demonstrate regression by 1 to 2 years, with apparently normal vessels on angiography or echocardiography.[155,158] The likelihood that an aneurysm will appear to regress by echocardiography or angiography is higher with smaller aneurysms, age younger than 1 year at the onset of Kawasaki disease, fusiform rather than saccular morphology, and involvement of a more distal coronary segment.[7,376] Regression of the internal diameter of the vessel to normal may occur by luminal smooth muscle cell–derived myofibroblastic proliferation or by thrombus organization and recanalization.[94,282,327] Intravascular ultrasound studies have been interpreted to suggest that thickened intima and media sometimes with calcifications are present in areas of apparently regressed coronary aneurysms.[119,362] However, direct correlation of intravascular findings and histology have not been performed. A very recent histologic study of 41 heart specimens demonstrated that calcification was found only in areas of organized thrombus not in vascular media or intima.[282] Regressed aneurysmal

segments are histologically abnormal and have abnormal functional responses with decreased vascular reactivity in response to exercise or pharmacologic agents such as isosorbide dinitrate or acetylcholine.[70,138,327,361] Only a limited number of regressed aneurysms progress to stenosis.[159,361,368,370]

Functional abnormalities of coronary vessel endothelium relaxation years after the onset of Kawasaki disease have been reported[70,138,234] and warrant further investigation. Newer imaging methods have demonstrated vascular wall changes sometimes even in patients with no history of abnormalities in the acute phase. The meaning of these findings in patients thought to have escaped coronary abnormalities with acute Kawasaki disease and their long-term significance are uncertain.

Patients with giant coronary aneurysms are at the greatest risk for the development of significant stenosis with resultant myocardial ischemia.[162,358] The risk for significant stenosis, usually developing at the inlet or outlet of a moderate to large coronary aneurysm, shows a steady rise over 15 to 20 years of observation.[150,162,358,363,368] These markedly abnormal vessels are subject to calcification and thrombosis, which may lead to myocardial ischemia or infarction. A recent analysis of 76 subjects with giant aneurysms from one Japanese center with median follow-up of 19 years showed 95 percent, 88 percent, and 88 percent 10-, 20-, and 30-year survival rates. Catheter and surgical coronary interventions resulted in 28 percent, 43 percent, and 59 percent cumulative coronary intervention rates at 5-, 15-, and 25-year follow-up.[358]

In 10- to 20-year follow-up studies of patients with Kawasaki disease, the arteries most likely to develop stenosis are the right main and left anterior descending coronary arteries.[150,162,358,363,368] A limited number of studies of young adults with ischemic heart disease and history of diagnosed Kawasaki disease or a compatible clinical illness have been performed.[61,160] A survey of Japanese adult cardiologists identified 130 adult patients with coronary aneurysms detected by angiography to evaluate myocardial infarction or ischemia.[160] Twenty-one of these patients (mean age, 34 years; range, 20 to 63 years) had a history compatible with Kawasaki disease in childhood. These patients had severe coronary disease with myocardial infarction, angina pectoris, mitral regurgitation, arrhythmias, congestive heart failure, and need for coronary bypass grafting. This study indicates that the coronary artery sequelae of Kawasaki disease likely are important causes of ischemic heart disease in young adults. Daniels and coworkers evaluated 261 adults younger than age 40 years who underwent angiography for suspected myocardial ischemia and found 16 with coronary aneurysms, 13 of whom had definite or presumed Kawasaki disease as the cause.[61] Fatty deposits and advanced changes resembling atherosclerotic disease sometimes have been found at autopsy of children with a history of Kawasaki disease who died of other causes.[374] This finding raises the important but unanswered question of whether patients with Kawasaki disease are at increased risk for developing premature or accelerated atherosclerosis. Gupta-Malhotra and colleagues reported higher levels of total cholesterol and apolipoprotein B but not increased carotid intimal-medial thickness or arterial stiffness by tonometry in patients who had Kawasaki disease 7 to 20 years earlier compared with control subjects.[118]

Long-Term Management

The risk for coronary artery thrombosis or stenosis that may result in myocardial ischemia and infarction remains the most important long-term clinical problem in the subset of patients with Kawasaki disease who develop significant coronary abnormalities (see Table 77-5). Patients have traditionally been classified as having small (<6 mm), medium (6 to 8 mm), and giant (>8 mm) aneurysms, and the latter two categories are at substantial risk for development of stenosis years after having the acute illness, compared with patients with small aneurysms or no aneurysmal changes.* Patients with giant aneurysms are at the highest risk for thrombosis.[262] Manlhiot and colleagues[216] documented that the American Heart Association classification scheme noted earlier underestimated the severity of coronary abnormalities and showed the following optimal definitions: small aneurysm, z-score of 2.5 to less than 5.0; large aneurysm, z-score greater than or equal to 5.0 to less than 10.0; and giant aneurysm, z-score greater than or equal to 10.0. Echocardiography and electrocardiography often are not sufficiently sensitive to detect stenotic lesions. Various stress tests for detection of reversible myocardial ischemia, including nuclear perfusion scans with exercise, exercise echocardiography, and stress echocardiography with agents such as dobutamine, dipyridamole, or adenosine, have been used in children to detect stenosis.[262,270,285] Newer techniques, including stress magnetic resonance imaging (stress MRI), MR angiography (MRA), and CT angiography (CTA) are being utilized.[45,117,291,379] Coronary arteriography has been the most definitive method to determine the degree of stenosis and the adequacy of collateral circulation but is invasive. Intravascular ultrasonography is an effective method to evaluate vascular wall morphology in selected patients during angiography.[364,367] All patients with evidence of myocardial ischemia or infarction should be studied by angiography to determine the need for intervention.[262] Most experts agree that patients with moderate to severe coronary artery aneurysms, a single large aneurysm, or multiple aneurysms should have their coronary anatomy defined by angiography or MRA or CTA at least once after the acute stage of illness (after the inflammatory process has subsided) to define fully the extent of involvement and to identify potential sites of thrombotic or stenotic complications.[262] Because aneurysms can also occur in noncoronary arteries, especially the subclavian, brachial, axillary, iliac, and femoral arteries, and occasionally in the abdominal aorta and renal arteries[369] (almost always in patients with coronary abnormalities), abdominal aortography and subclavian arteriography are recommended for patients with Kawasaki disease who are undergoing coronary angiography for the first time.[262]

Patients who have had Kawasaki disease are divided into five risk levels for long-term management by the American Heart Association, as outlined here.[262]

*References 7, 150, 155, 158, 162, 369, 404.

Patients with No Evidence of Coronary Artery Abnormalities at Any Time (Risk Level I)

Patients who have never manifested coronary artery abnormalities have no need for aspirin or other antiplatelet medication beyond 6 to 8 weeks after onset of illness or for restriction of physical activities in the convalescent stage. Only routine pediatric follow-up beyond 1 year, with routine cardiovascular risk assessment, is indicated.

Patients with Transient Coronary Ectasia or Dilation (Risk Level II)

Patients with transient coronary artery abnormalities that resolve by 6 to 8 weeks should be treated with aspirin 3 to 5 mg/kg/day until resolution of abnormalities. No restrictions are indicated after 6 to 8 weeks, angiography is not indicated, and risk assessment and counseling are recommended at 3- to 5-year intervals.[360]

Patients with Isolated (Solitary) Small to Medium (3- to 6-mm) Coronary Aneurysm in One or More Coronary Arteries (Risk Level III)

Patients with solitary small to medium coronary artery aneurysms should be maintained on daily low-dose aspirin 3 to 5 mg/kg at least until apparent regression is documented with annual echocardiographic follow-up.[360] For patients younger than 11 years old, no restriction on physical activity is indicated, but for those 11 years old and older, physical activity should be guided by a biennial stress test or myocardial perfusion test. Angiography should be performed if stenosis or ischemia is suggested.

Patients with One or More Large (>6-mm) or Giant (>8-mm) Coronary Aneurysm, or Multiple (Segmented) Smaller or Complex Aneurysms Without Obstruction (Risk Level IV)

Long-term antiplatelet therapy with aspirin 3 to 5 mg/kg once daily or clopidogrel 1 mg/kg/day up to adult dose of 75 mg is indicated for these children and should be continued indefinitely. Anticoagulant therapy with warfarin, with the international normalized ratio (INR) maintained at 2.0 to 2.5, or daily subcutaneous low-molecular-weight heparin should be added for patients with giant aneurysms because these patients are at substantial risk for coronary thrombosis. All such patients should be under the care of a pediatric cardiologist with experience in managing patients with Kawasaki disease. Cardiac evaluation with an echocardiogram and an electrocardiogram should be performed approximately every 6 months, with stress testing performed approximately annually. Angiography should be performed 6 to 12 months after the patient has recovered from the acute stage of disease to define the coronary anatomy, and it should be repeated whenever symptoms or stress tests suggest the presence of myocardial ischemia. Physical activity should be regulated on the basis of annual stress test results and level of anticoagulation, and participation in strenuous or contact athletics should be discouraged.

Patients with Coronary Artery Obstruction (Risk Level V)

Patients with obstructive lesions or signs of myocardial ischemia should be evaluated urgently for possible intervention. Balloon angioplasty, rotablator angioplasty, coronary artery bypass grafting, stent placement, and even cardiac transplantation all have been employed for patients with Kawasaki disease who have particularly serious coronary artery disease.[6,49,116,142,244,405] Arterial bypass grafts are superior to venous grafts in these patients.[174] Balloon angioplasty procedures have been associated with high rates of recurrent stenosis in patients with Kawasaki disease and coronary stenosis.[6]

TABLE 78-1 Centers for Disease Control and Prevention 1994 Workshop Case Definition of Chronic Fatigue Syndrome

1. Fatigue (persistent or relapsing) that has new or definite onset, is of >6 months' duration, and leads to a substantial (>50%) reduction in level of activity
   plus
2. At least four of the following:
   Impaired memory or concentration
   Sore throat
   Tender lymph nodes: cervical or axillary
   Myalgias
   Arthralgias (multiple joints, without swelling or erythema)
   New onset (or in severity) of headaches
   Unrefreshing sleep (hypersomnia or insomnia)
   Postexertional fatigue lasting >24 hours
   and
3. The absence of another diagnosis for the individual's signs and symptoms

Modified from Fukuda K, Straus SE, Hickie I, et al. The chronic fatigue syndrome: a comprehensive approach to its definition and study. *Ann Intern Med* 1994;**121**:953–9.

despite similar arrays of signs and symptoms, patients with CFS likely represent a heterogeneous population. Still, evaluation of groups of patients with this symptom-complex has provided information about pathophysiologic changes occurring in patients with CFS and potentially beneficial, although not curative, approaches to therapy for affected individuals have been developed.

In an attempt to provide a degree of uniformity as a basis for research into the evaluation of such patients, the U.S. Centers for Disease Control and Prevention (CDC) developed a definition of CFS in 1988.[47] These criteria were revised in 1994, with physical signs removed from the definition because they appeared to be unreliably documented in studies, and the required number of symptoms for the diagnosis of CFS decreased from 8 of a list of 11 to 4 of 8 components (Table 78-1).[38] These changes, being less restrictive, may serve to increase the sensitivity of the diagnosis, but they also decrease the specificity. However, these criteria are purely speculative in the absence of any gold standard or definitive diagnostic test for CFS. These 1994 criteria also suggest subdivisions of patients with CFS for research purposes and provide guidelines for nonresearch clinicians as well. Other international groups have generated similar definitions of CFS for evaluating this condition.[16,65,93]

The primary manifestations of CFS are severe fatigue of more than 6 months' duration that limits activity to less than 50 percent of premorbid function and the association of multiple other symptoms, as outlined in the case definitions of CFS.[38,47,65,93] These symptoms include new or more intense headaches, decreased ability to focus or concentrate, recurrent sore throats, a sensation of tender cervical or axillary lymph nodes, low-grade temperature elevations, myalgias and arthralgias, postexertional fatigue lasting longer than 24 hours, and sleep disturbances (hypersomnia or insomnia). The severity and persistence of these findings vary among individual patients with CFS. In addition, although not included in the case definitions, many patients report dizziness, especially with changes in position, feeling hot when others are cold or vice versa, chronic costochondritis, and a Raynaud-like phenomenon.

HISTORICAL OVERVIEW

In all likelihood, CFS is not a new illness. Numerous conditions with features comparable to those of CFS have appeared in the medical literature during the past several centuries.[107] Many of these descriptions attempted to associate an illness characterized by prolonged debilitating fatigue and numerous other symptoms with an infectious agent. They have included chronic brucellosis,[100] chronic enteroviral syndrome,[21,25,42] chronic candidiasis,[87] myalgic encephalomyelitis,[2] chronic mononucleosis (Epstein-Barr virus [EBV] infection),[4,49,112,113] human herpesvirus–6 infection,[11,120] human herpesvirus–7 infection,[30] chronic Lyme disease,[101] parvovirus B19 infection,[55] and a new retroviral infection.[27] Noninfectious conditions described with similarities to CFS include total-allergy syndrome, hypoglycemia, neurasthenia, Iceland disease, Royal Free disease, and fibromyalgia rheumatica.[59] In addition to clinical similarity to CFS, all these conditions, at least at the time they were described, lacked a diagnostic test to confirm a definitive causative agent and, in their acute form, manifested as fatigue in association with multiple other complaints.

A review of the experience in the mid 1980s associated groups of patients with CFS-like illness with patients with chronic EBV infection.[4,49,112] These reports described elevated and aberrant patterns of EBV antibody responses in individuals with prolonged fatigue and multiple symptoms consistent with CFS. Acute infectious mononucleosis also often manifests as fatigue, fever, malaise, sore throat, lymphadenitis, and multiple systemic complaints, although typically in a more pronounced manner. Subsequent studies, however, revealed that the elevation or pattern of EBV antibody responses in such patients was not consistently different from findings in others who resolved symptoms of acute EBV infection.[73] Additionally, shedding of EBV in secretions was not increased in these individuals and no association was found between viral shedding and severity of symptoms.[114] Furthermore, no response to the antiviral drug acyclovir occurred in a group of such patients in a placebo-controlled, double-blind crossover study in terms of improvement of clinical symptoms.[109] After these observations were made, the name *chronic fatigue syndrome* was chosen to define this illness,[47] at least until a specific cause or marker for this illness is identified.

Cameron and colleagues reported on a cohort of patients with prolonged fatigue after having infectious mononucleosis. No difference in EBV load was demonstrated in eight patients with 6 months or more of disabling symptoms after the diagnosis of infectious mononucleosis was established, and again there was a lack of correlation between persistent symptoms and

viremia or altered host responses to EBV.[14] Despite the lack of association of ongoing EBV infection with CFS, Katz and colleagues observed that infectious mononucleosis may be an antecedent risk factor for CFS in adolescents.[54]

Recently increased detection of nucleic acid of a xenotropic murine leukemia virus (XMRV), a newly discovered retrovirus, was reported in two different series of CFS patients.[67,68] Subsequent studies failed to confirm these observations, including two reports that utilized samples from the same patients reported in the two positive studies just cited.[5,46,96,116] Contamination of the assays in the positive studies may have been responsible for the positive results, and both of those studies were subsequently retracted.[3,43,95]

EPIDEMIOLOGY

The definitions of CFS allow for attempts to characterize the prevalence and demographic features of this condition. Still, given the vagaries of the symptom-complex, possible variations in application of the diagnosis by different health care providers, and the potential differences within groups of people to seek medical attention for this condition, data reported on these issues may not be a complete representation of the epidemiology of this condition. CFS has been reported in all age groups, including children as young as 5 years of age, and in all ethnic, racial, and socioeconomic groups, but most CFS cases have been reported to occur in middle- to upper-class white women with a median age of 35 to 40 years.[58] Based on a study of physician-diagnosed patients from four cities using the 1988 case definition of CFS,[1] the CDC estimates a minimum prevalence rate of CFS of 2 to 10 cases per 100,000, or higher, in adults aged 18 years and older in the United States.[12,70,84] A population-based descriptive epidemiologic study conducted by the CDC in Kansas estimated the prevalence of CFS to be 235 per 100,000 persons and a 1-year incidence to be 180 per 100,000 persons.[88] Studies from outside the United States have reported similar or higher prevalence rates of CFS in adults.[31,65]

Although the CDC definition does not include age criteria for the diagnosis of CFS, the prevalence of CFS in the pediatric age range has not been studied well. Some researchers have suggested that the diagnosis of CFS should not be used in children, to avoid potential delay in making an alternative medical or psychological diagnosis.[83] However, many referral centers have reported groups of pediatric patients, primarily adolescents, with features and a clinical course similar to those reported in adults.* Furthermore, in these studies, missed or alternative diagnoses were not found, despite years of follow-up. Rimes and colleagues reported prevalence rates of CFS in an adolescent population similar to those reported in adults.[89]

In these pediatric studies, a predominance of female patients with a median age of 14 years at the time of diagnosis was noted. Additionally, these patients were from predominately middle- to upper-class families, and, as discussed later, their signs and symptoms at presentation (Table 78-2) and their course of illness were similar to those reported in adults with CFS. CDC studies suggest that the prevalence of CFS in adolescents approaches that reported in adults, but cases in children younger than 12 years of age occur much less often.[38] One suggestion is that a shorter duration of symptoms (3 to 4 months vs. 6 months) may be appropriate for establishing the diagnosis of CFS in pediatric patients.[38,50] Multiple family members with CFS may be seen as well, but, to date, evidence that CFS is contagious does not exist.

TABLE 78-2 **Symptoms Reported by 58 Children and Adolescents Evaluated for Chronic Fatigue Syndrome (1989 to 1994)**

Symptom	No. Patients	Percentage (%)
Fatigue	58	100
Headache	43	74
Sore throat	34	59
Abdominal pain	28	48
Fever	21	36
Impaired cognition	19	33
Myalgia	18	31
Diarrhea	17	29
Adenopathy	17	29
Anorexia	16	28
Nausea/vomiting	15	26
Congestion	13	22
Dizziness	10	17
Arthralgia	10	17
Otitis	6	10
Cough	6	10
Rash	5	9
Sweats	5	9
Chills	4	7
Depression	4	7

ETIOLOGY AND PATHOGENESIS

Infection

As noted previously, an infectious origin of CFS has not been demonstrated and a single microorganism as the cause of CFS is unlikely. However, an acute infection appears possibly to play a role in precipitating CFS because most (as many as two thirds) patients with CFS relate a sudden onset of their symptoms to an acute infection, most often infectious mononucleosis. Lyme disease[69,101] and an influenza-like illness[48] also have been reported in association with the onset of CFS.

*References 7, 17, 32, 61, 71, 99.

Immunologic Dysfunction

A role for immunologic dysfunction in CFS has been suggested, based on numerous studies demonstrating abnormalities in lymphocyte function or cytokine production.* However, these findings have not been reproducible in different groups of patients with CFS. Some evidence suggests that nonspecific elevation of antibody titers and an increase in allergic symptoms occur in patients with CFS.[110] However, these findings are mild, and similar immunologic changes may be seen in other conditions, including depression. Individuals with CFS may report an increased frequency and duration of infections compared with their pre-CFS state, but they tend to be mostly routine viral illnesses. Neither unusual nor opportunistic infection nor increased risk for developing malignant disease has been observed in these individuals. Intravenous immunoglobulin infusions have not demonstrated long-term clinical benefit when they are administered to patients with CFS and may cause significant adverse reactions.[66,82,106]

Genetic Components

A number of recent studies of gene expression from peripheral blood samples have identified potential gene patterns associated with neuroendocrine function, stress reactions, and immune responses that may be associated with CFS.[45,56] Further definition of such genes may help further establish a biologic basis for development of CFS and eventually lead to diagnostic tests for CFS and targeted approaches to therapy.

Some studies have focused on potential genetic markers of CFS using DNA microarray technology.[102] An analysis of cytokine gene polymorphisms in 80 Italian patients with a diagnosis of CFS assessed using the 1994 CDC definition reported significant difference in tumor necrosis factor and interferon-γ phenotypes compared with controls. The authors hypothesized a potential altered immunologic or inflammatory response based on these differences as potentially contributing to the pathogenesis of CFS.[10,15,35] An analysis of prolonged postinfectious fatigue in patients who had had mononucleosis identified certain genes involved in immune responses, and hormonal and neurologic pathways that were altered in a subset of patients with mononucleosis were associated with the development of prolonged fatigue.[14,41,98] If reproducible gene expression markers are confirmed, they could potentially be used as diagnostic tools for CFS.

CLINICAL MANIFESTATIONS

Neurologic Factors

Many patients with CFS report cognitive impairment manifest as a decreased ability to concentrate and focus, difficulty in processing information, and trouble with word recall. Complaints of headache (new onset or altered pattern) and other neurologic symptoms, such as paresthesias and dysequilibrium, also are reported commonly by patients with CFS.

Despite these complaints, physical examination does not reveal abnormal neurologic signs. Formal neuropsychometric testing also may not reveal objective abnormalities to the extent reported by the patient. Whether this discrepancy reflects a problem with testing methods or altered perception on the part of the individual is uncertain at this time.[11,79]

Magnetic resonance imaging (MRI) has been reported to show an increase in cerebral white matter abnormalities in patients with CFS.[11,78,91] Similarly, in many studies, single photon emission computed tomography (SPECT) has demonstrated changes in perfusion in certain areas of the brain in patients with CFS.[23,34,92] In other studies, however, abnormalities specific to CFS have not been observed consistently and methodological concerns have been raised regarding the interpretation of abnormal findings cited previously.[22,44] An abnormality at the base of the fourth ventricle detected on focal computed tomography (CT) of the base of the brain and responding to neurosurgical intervention was reported in a group of patients with CFS,[40] but this defect is not seen on routine CT or MRI and requires confirmation by other researchers before determining its significance for these patients. At present, imaging of the central nervous system is not indicated routinely in the evaluation of a patient with CFS.

Endocrinologic Factors

Subtle defects in the hypothalamic-pituitary-adrenal axis have been described in cohorts of patients with CFS. These abnormalities include decreased free urinary cortisol levels and exaggerated adrenal responsiveness to corticotropin infusion.[29] These changes are quantitatively minor, and mean values are still within normal for age and sex, thus rendering these values unreliable as a diagnostic test for CFS. Similar changes have been described in patients with fibromyalgia and post-traumatic stress disorder.

Cardiovascular Factors

In 1995, investigators at Johns Hopkins Hospital in Baltimore described a cohort of seven adolescents with chronic fatigue and autonomic dysfunction as assessed by tilt-table testing.[90] Furthermore, these patients reported improvement or resolution of symptoms, including fatigue, with treatment of their orthostatic intolerance. Further studies from this group demonstrated some component of orthostatic hypotension in 92 percent of patients with CFS.[9] Studies in groups of adults, in contrast, showed tilt-table test abnormalities in only 25 to 40 percent of patients.[36,97] Whether this finding reflects true age-related differences in this phenomenon in patients with CFS is uncertain, given potential methodological differences in the performance of the tests.

The pattern of orthostatic intolerance among adolescents with CFS was characterized further by Stewart and colleagues and is consistent with the postural orthostatic

*References 13, 57, 64, 74, 108, 111, 115.

tachycardia syndrome (POTS).[103-105] Symptoms of POTS may develop after an acute infectious illness or with severe deconditioning and include fatigue, lightheadedness, impaired cognition, inappropriate sweating, headache, palpitations, nausea, vomiting, and tremulousness. These authors suggest that CFS may be an extreme expression of POTS in at least some cases.

The importance of these cardiovascular findings in CFS remains unsettled. Subjective components may contribute to defining a tilt-table test as abnormal because these studies are not performed blinded. Some healthy individuals also may experience hypotension during these tests. Further studies defining the effect of treatment of POTS on the course of CFS should help to answer this question. In this context, evaluation of, and therapy for, orthostatic changes, especially if dizziness is a significant component of the patient's complaints, may be indicated.[128]

Sleep Physiology

Sleep disturbances have been described in selected groups of patients with CFS, and some of these conditions may be amenable to therapy.[63,86] However, no single pattern of sleep abnormality has been reported for these patients, and, in our experience, the pattern of hypersomnia or insomnia tends to improve as the patient recovers.[117]

Psychological Factors

Psychological factors have been considered in the origin and perpetuation of CFS. Adults with CFS have demonstrated a higher frequency of depression and other psychiatric disorders before the onset of their CFS compared with age-matched controls.[1,62] Certainly, many of the symptoms reported in CFS also are reported commonly in depression. They may include sleep disturbances, loss of energy, difficulty in concentrating, changes in appetite, and musculoskeletal complaints. Studies in children and adolescents with CFS also have shown significant psychological features, especially depression and somatization, compared with both healthy controls and those with other chronic illnesses (e.g., juvenile idiopathic arthritis, cancer, cystic fibrosis).[17,18,50,80,122] Still, certain features of CFS argue against its being solely a variant of depression. Individuals with CFS do not have the mood-related symptoms reported in patients with clinical depression. These mood-related symptoms include negative affect, anhedonia, low self-esteem, and suicidal ideation. Furthermore, patients with CFS and their families have a firm belief that an infectious, immunologic, or other medical cause for their symptoms exists, and the patients desire a return to normal activities.

In considering the possible link between depression or psychological stress and CFS, several possible relationships may exist. Preexisting depression or stress may create a psychological vulnerability that allows for the development of CFS in combination with any of numerous other factors discussed previously. Studies have demonstrated a role for psychological factors predicting the response to mononucleosis and influenza.[48,52] Similar factors may be involved in the development of CFS. Alternatively, depression may be a physiologic consequence of the central nervous system changes that occur in those who develop CFS, just as decreased concentration and memory occur as part of the syndrome.[50,122] Furthermore, reactive depression may occur in these patients in response to the inability to participate in their usual activities and to absence from school and separation from friends. Finally, CFS may be, at least in some cases, a manifestation of separation anxiety or school phobia in which secondary gain, as a conversion reaction, is playing a major role. Certainly, at least a subset of adolescents and children with CFS in our experience does not appear eager to return to school or activities, and secondary gain may play a role in the perpetuation of their illness.[48]

In summary, each of these potential links between depression or stress and CFS likely plays a role, with the relative contribution of each feature varying for different people. This suggestion is consistent with the overall hypothesis that many different factors appear to contribute to the development and perpetuation of CFS. The relative contribution of these different features may vary from individual to individual and even for the same patient over the course of the illness. The assessment and management of the patient with CFS should attempt to consider these issues and their relative importance for that individual.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of CFS is one of exclusion and requires a comprehensive history. In the pediatric population, this information is obtained best from the patient and parents. Additionally, we request that families bring prior medical records, test results, and pertinent school records to facilitate a complete evaluation. This process may be lengthy because the details are complicated, of long standing, and often a source of debate between the patient and parents. The history should focus on the onset of illness, the duration and severity of symptoms, prior evaluations (often multiple) as well as medical history before the illness, family history, academic performance, and social history. The physical examination of the individual with suspected CFS almost always is essentially normal despite the multitude of symptoms. Findings of mild pharyngeal erythema and cervical adenopathy commonly are reported. However, finding fever, weight loss, significant adenopathy, or organomegaly should alert the clinician to the possibility of an alternative diagnosis.

DeMeirleir and colleagues reported increased detection of a 37-kDa, 2-5A-synthetase binding protein in peripheral blood mononuclear cells from patients with CFS compared with healthy controls.[28] These binding proteins are related to the ribonuclease L antiviral pathway of these cells. This finding requires further confirmation before it can be considered a potential diagnostic test for CFS. At present, no specific tests for diagnosing CFS exist and laboratory testing is aimed primarily at eliminating other possible diagnoses. Most patients have undergone multiple laboratory tests before a diagnosis of

CFS has been considered, but these tests may be repeated or completed as part of the initial CFS evaluation. Additionally, interpreting previously performed tests may be part of the initial patient assessment. Screening studies may include a complete blood cell count with differential and platelets, erythrocyte sedimentation rate, hepatic and renal function studies, urinalysis, and thyroid function tests. Additional tests that may be indicated based on history and physical examination may include toxicology screening, human immunodeficiency virus serology, antinuclear antibody, rheumatoid factor, tuberculin skin test, and cortisol level. Serologic evaluations for EBV, Lyme disease, and group A streptococcal infection may be requested based on history and physical infection. In most instances, these tests are not indicated; however, they often are obtained before CFS is suspected, and they need to be appropriately reviewed or repeated as part of the initial evaluation for CFS. Screening radiographic studies may include a chest radiograph or imaging of the paranasal sinuses based on the patient's symptoms.

Elimination of every possible disorder that may cause a patient to experience prolonged fatigue is impossible; but when guided by history, physical examination, and laboratory screening tests as outlined previously, the clinician can make a reliable diagnosis of CFS. Follow-up for periods of 4 to 13 years for pediatric patients diagnosed with CFS have not identified cases of missed or alternative diagnoses for their complaints.[6,61] In general, the longer the duration and the greater the number of symptoms, the less the need for extensive laboratory evaluations to suggest the diagnosis of CFS. Conversely, alternative diagnoses should be considered if a single symptom dominates the clinical presentation or if physical examination or laboratory tests reveal significant abnormalities.

Psychosocial assessment is indicated for all children and adolescents presenting for CFS evaluation. The extent of such evaluation may be limited to assessment by primary care personnel or may include collaboration with a social worker, psychologist, or psychiatrist, based on the individual's needs and the comfort level of the examiner. Cardiopulmonary and neurologic evaluations may be used in some cases, both to consider possible alternative diagnoses and to assist in assessing factors that may be contributing to the symptoms of CFS.

MANAGEMENT

One of the essential qualities of the clinician is interest in humanity, for the secret of care of the patient is in caring for the patient.

DR. FRANCIS PEABODY, 1926 (WALL PLAQUE, LOBBY OF THE MASSACHUSETTS GENERAL HOSPITAL, BOSTON)

Management of patients with CFS is aimed at providing a combination of supportive treatment and emotional support (Table 78-3).[37] This process can be initiated during the initial evaluation, with a discussion of the diagnostic criteria for CFS and a review of the results of previously obtained laboratory tests. The relationship between physical and psychological symptoms can be explained, and the patient and family can be reassured that symptoms are real, even if the symptoms have psychiatric components. Additionally, the patient and family can be advised that most children and adolescents with CFS do well over time[6,32,60,61] and have a better long-term outlook than that described for adults with CFS.[51,127] Furthermore, emphasizing the frequent ups and downs in symptoms that generally characterize the course of CFS is important in assisting the patient and family to develop coping skills. This assistance may include guidance on how to modify lifestyle most appropriately and how to set realistic schedules and goals. Studies from the United Kingdom suggest that formal cognitive-behavioral therapy[26,85,94,126] or graded exercise programs, or both, may be beneficial for patients with CFS.[19,39,123,125]

Many other therapies have been advocated by different groups for patients with CFS. These treatments may include supplements, such as essential fatty acids,[121] magnesium,[24] liver extract injections,[53] and vitamin and nutritional supplements,[72] as well as pharmacologic treatments, such as corticosteroids,[20,75,81] reduced nicotinamide adenine dinucleotide,[118] antidepressants,[77,119] and growth hormone.[76] A recent brief observation report suggested that methylphenidate may be beneficial in relieving fatigue and improving concentration in some patients with CFS.[8] Homeopathic therapies, osteopathy, and massage therapy[33] also have been reported to be beneficial in the management of CFS. Most of these approaches have not been studied adequately to allow definitive comment on their potential benefit for a given patient. Still, the clinician should be aware of them, to help guide patients who are likely to hear about them from other patients or outside sources, including the internet.[40,124,126]

TABLE 78-3 **Approach to Management of Chronic Fatigue Syndrome in Children and Adolescents**

- Evaluation and explanation of the diagnosis, including overview of multifactorial components
- Reassurance that symptoms are real
- Anticipatory guidance regarding secondary problems, up-and-down course of syndrome, secondary gain
- Coping skills: lifestyle modification, decreased stress, and realistic expectations and schedule
- Cognitive behavioral approaches: gradual increases in activity, an exercise program, attention to sleep patterns, attention to nutrition
- Psychological support for individual and family
- Educational issues: return to classes, home tutors, neuropsychiatric testing as indicated
- Relationship issues: friends and family
- Follow-up plan: monitoring of physical symptoms and psychological issues, ongoing guidance and reassurance (follow-up visits every 4 to 6 weeks)
- Minimize shopping for a doctor, unnecessary testing, family strain, and unconventional, unproven, or experimental therapies

Modified from Krilov LR, Fisher M: Chronic fatigue syndrome in children and adolescents. *Contemp Pediatr* 2002;**19**:61–8.

PROGNOSIS AND FUTURE DIRECTIONS

CFS likely affects heterogeneous groups of patients, and a single cause or definitive treatment modality most likely will not be uncovered. Nonetheless, studying groups of such patients yields helpful information on the pathophysiology of this condition, and useful steps to address and alleviate symptoms for patients have been reported. In recognition of the significance of this entity, the CDC launched an awareness campaign, including the development of an internet site for health care professionals and the public.* In addition, long-term follow-up data demonstrating improvement over the course of time, especially in children and adolescents, without emergence of significant other conditions, are encouraging for patients, families, and clinicians caring for such individuals.

BACTERIAL INFECTIONS

CHAPTER 79

Nomenclature for Aerobic and Anaerobic Bacteria

David A. Bruckner

Table 79-1 represents an update of the current nomenclature, taxonomy, and classification of various microbial agents and is based on the organism's morphologic and stain characteristics. Organisms included are those that often are associated with pathologic processes or that are medically significant. The current names are those either officially recognized or proposed for recognition and currently used in the literature. Some organisms listed have been characterized, but have never been cultured.

Taxonomic ranks for naming bacterial organisms include kingdom, division, class, order, family, genus, species, and subspecies. All of these ranks have official standing in nomenclature. Ranks below subspecies have no official standing but are used to indicate groups of strains or isolates that can be distinguished by some special characteristics (Table 79-2). Each taxonomic name should be represented by a nomenclature type. The species is represented by a type strain that is deposited in recognized culture collections.[4] Nomenclature priorities for bacteriologic names date back to May, 1753. Because of difficulties in searching the literature and limited available information on described species, approved lists of bacterial names were published in the *International Journal of Systematic Bacteriology* in 1980. Names not included on those lists have lost all standing in nomenclature status.

Historically, bacterial classification has been based on phenotypic characteristics. Multivariate analysis has played a large role in classification since the 1950s. This analysis used biochemical, cultural, and morphologic characteristics and susceptibilities to antibiotics and inorganic compounds to define the degrees of similarities among organisms. More recently, molecular techniques (e.g., DNA hybridization, rRNA-DNA hybridization, gene sequence analysis, and multilocus sequence analysis) have played a major role in determining phylogenetic relationships. The DNA molecular weight for most bacteria is 1×10^9 to 8×10^9 D, enough to specify 1500 to 6000 genes. Using nucleic acid analysis, researchers have developed numerous parameters to determine taxonomic relationships. By correlating phenotypic results with DNA homology and rRNA sequence analysis, researchers have been able to select phenotypic tests that can be used more accurately to identify organisms belonging to specific groups.[3,7] Molecular methods have helped to define groupings of organisms and have led to considerable changes in bacterial nomenclature. The primary purpose of nomenclature is to permit us to know as exactly as possible what another clinician, microbiologist, epidemiologist, or investigator is referring to when describing an organism responsible for infecting individuals or for causing an outbreak. The *International Code of Nomenclature of Bacteria*[5] includes rules on how to name bacteria and use the name. The most comprehensive taxonomic information available for bacteriologic classification can be found in *Bergey's Manual of Systematic Bacteriology*,[1,2] volumes 1 through 4. Names are validated only when they are included in the validation lists regularly published by the *International Journal of Systematic and Evolutionary Microbiology*.[4,6] An overview of validly published names can be obtained at http://www.bacterio.cict.fr or http://www.dsmz.de/microorganisms/bacterial_nomenclature.php.

TABLE 79-1 Current Bacterial Nomenclature, Taxonomy, and Classification

I. Aerobic Gram-Positive Cocci

Characteristics: Aerotolerant anaerobes that can occur singly or in pairs, tetrads, chains, or clusters; they can be catalase-positive or catalase-negative. Organisms positive for coagulase or clumping factor include *Staphylococcus aureus, Staphylococcus intermedius, Staphylococcus lugdunensis,* and *Staphylococcus schleiferi* subspecies *coagulans*.

Current Name	Synonym
Catalase-Positive Organisms	
Alloiococcus otitidis	*Alloiococcus otitis*
Auritidibacter ignavus	
Kocuria carniphila	
Kocuria kristinae	*Micrococcus kristinae*
Kocuria rhizophila	
Kocuria rosea	*Micrococcus roseus*
Kocuria varians	*Micrococcus varians*
Kytococcus schroeteri	
Kytococcus sedentarius	*Micrococcus sedentarius*
Micrococcus luteus	
Micrococcus lylae	
Staphylococcus arlettae	
Staphylococcus aureus subspecies *anaerobius*	
Staphylococcus aureus subspecies *aureus*	
Staphylococcus auricularis	
Staphylococcus capitis subspecies *capitis*	
Staphylococcus capitis subspecies *ureolyticus*	
Staphylococcus caprae	
Staphylococcus carnosus subspecies *carnosus*	
Staphylococcus carnosus subspecies *utilis*	
Staphylococcus chromogenes	*Staphylococcus hyicus* subspecies *chromogenes*
Staphylococcus cohnii subspecies *cohnii*	
Staphylococcus cohnii subspecies *urealyticus*	
Staphylococcus condimenti	
Staphylococcus delphini	
Staphylococcus epidermidis	*Staphylococcus albus*
Staphylococcus equorum subspecies *equorum*	
Staphylococcus equorum subspecies *linens*	
Staphylococcus felis	
Staphylococcus fleurettii	
Staphylococcus gallinarum	
Staphylococcus haemolyticus	
Staphylococcus hominis subspecies *hominis*	
Staphylococcus hominis subspecies *novobiosepticus*	
Staphylococcus hyicus	
Staphylococcus intermedius	
Staphylococcus kloosii	
Staphylococcus lentus	*Staphylococcus sciuri* subspecies *lentus*
Staphylococcus lugdunensis	
Staphylococcus lutrae	
Staphylococcus muscae	
Staphylococcus nepalensis	
Staphylococcus pasteuri	
Staphylococcus pettenkoferi	
Staphylococcus piscifermentans	
Staphylococcus pseudintermedius	
Staphylococcus saccharolyticus	*Peptococcus saccharolyticus*
Staphylococcus saprophyticus subspecies *bovis*	*Micrococcus* subgroup 3
Staphylococcus saprophyticus subspecies *saprophyticus*	
Staphylococcus schleiferi subspecies *coagulans*	
Staphylococcus schleiferi subspecies *schleiferi*	
Staphylococcus sciuri subspecies *carnaticus*	
Staphylococcus sciuri subspecies *rodentium*	
Staphylococcus sciuri subspecies *sciuri*	
Staphylococcus simiae	
Staphylococcus simulans	
Staphylococcus succinus subspecies *casei*	
Staphylococcus succinus subspecies *succinus*	
Staphylococcus warneri	
Staphylococcus xylosus	
Catalase-Negative Organisms	
Abiotrophia defectiva	*Streptococcus defectivus* Nutritionally variant streptococci
Aerococcus christensenii	
Aerococcus sanguinicola	*Aerococcus sanguicola*
Aerococcus urinae	
Aerococcus urinaehominis	
Aerococcus viridans	
Dolosicoccus paucivorans	
Dolosigranulum pigrum	
Enterococcus avium	*Streptococcus avium* Group D *Enterococcus*
Enterococcus caccae	
Enterococcus casseliflavus	*Enterococcus flavescens* *Streptococcus casseliflavus*
Enterococcus cecorum	*Streptococcus cecorum*
Enterococcus dispar	
Enterococcus durans	*Streptococcus durans* Group D *Enterococcus*

Continued on following page

TABLE 79-1 **Current Bacterial Nomenclature, Taxonomy, and Classification** (Continued)

Current Name	Synonym
Enterococcus faecalis	*Streptococcus faecalis* Group D *Enterococcus*
Enterococcus faecium	*Streptococcus faecium* Group D *Enterococcus*
Enterococcus gallinarum	*Streptococcus gallinarum*
Enterococcus gilvus	
Enterococcus hawaiiensis	
Enterococcus hirae	
Enterococcus italicus	*Enterococcus saccharominimus*
Enterococcus malodoratus	
Enterococcus mundtii	
Enterococcus pallens	
Enterococcus pseudoavium	
Enterococcus raffinosus	
Enterococcus sanguinicola	
Facklamia hominis	
Facklamia ignava	
Facklamia languida	
Facklamia sourekii	
Gemella bergeri	*Gemella bergeriae*
Gemella haemolysans	*Neisseria haemolysans*
Gemella morbillorum	*Streptococcus morbillorum* *Peptostreptococcus morbillorum*
Gemella sanguinis	
Globicatella sanguinis	Salt-tolerant viridans streptococci
Granulicatella adiacens	*Abiotrophia adiacens* *Streptococcus adiacens* Nutritionally variant streptococci
Granulicatella elegans	*Abiotrophia elegans* Nutritionally variant streptococci
Granulicatella para-adiacens	
Helcococcus kunzii	
Helcococcus pyogenica	
Helcococcus sueciensis	
Ignavigranum ruoffiae	
Lactococcus garvieae	*Streptococcus garvieae* Lancefield group N
Lactococcus lactis	
Leuconostoc citreum	
Leuconostoc dextranicum	
Leuconostoc lactis	
Leuconostoc mesenteroides	
Leuconostoc pseudomesenteroides	
Oenococcus oeni	*Leuconostoc oenos*
Pediococcus acidilactici	
Pediococcus damnosus	
Pediococcus dextrinicus	
Pediococcus equinus	*Streptococcus equinus*
Pediococcus parvulus	
Pediococcus pentosaceus	
Streptococcus acidominimus	
Streptococcus bovis group	Group D streptococci
Streptococcus alactolyticus	
Streptococcus bovis	
Streptococcus equinus	
Streptococcus gallolyticus subspecies *gallolyticus*	*S. bovis* biotype I
Streptococcus gallolyticus subspecies *macedonicus*	*S. bovis* biotype II.1
Streptococcus gallolyticus subspecies *pasteurianus*	*S. bovis* biotype II.2
Streptococcus infantarius subspecies *coli*	
Streptococcus infantarius subspecies *infantarius*	
Streptococcus anginosis group	Viridans streptococci
Streptococcus anginosus	
Streptococcus constellatus subspecies *pharyngis*	
Streptococcus intermedius	
***Streptococcus mitis* group**	Viridans streptococci
Streptococcus australis	
Streptococcus cristatus	
Streptococcus gordonii	
Streptococcus infantis	
Streptococcus mitis	*Streptococcus mitior* *Streptococcus sanguis* II
Streptococcus oligfermentans	
Streptococcus oralis	
Streptococcus orisratti	
Streptococcus parasanguinis	
Streptococcus peroris	
Streptococcus pneumoniae	*Diplococcus pneumoniae*
Streptococcus pseudopneumoniae	
Streptococcus sanguinis	
Streptococcus sinensis	
***Streptococcus mutans* group**	*Viridans streptococci*
Streptococcus cricetus	
Streptococcus mutans	
Streptococcus ratti	
Streptococcus sobrinus	
***Streptococcus pyogenes* group**	
Streptococcus agalactiae	Group B streptococci
Streptococcus canis	
Streptococcus dysgalactiae subspecies *equisimilis*	Group C streptococci
Streptococcus equi subspecies *zooepidermidis*	*Streptococcus equi* *Streptococcus equisimilis*
Streptococcus iniae	Group G streptococci *Streptococcus shiloi*
Streptococcus porcinus	
Streptococcus pyogenes	Group A streptococci

TABLE 79-1 **Current Bacterial Nomenclature, Taxonomy, and Classification** (Continued)

Current Name	Synonym
Streptococcus salivarius group	Viridans streptococci
Streptococcus salivarius	
Streptococcus thermophilus	
Streptococcus vestibularis	
Streptococcus suis	
Tetragenococcus halophilus	*Pediococcus halophilus*
Tetragenococcus solitarius	*Enterococcus solitarius*
Vagococcus fluvialis	
Weissella paramesenteroides	*Leuconostoc paramesenteroides*
II. Anaerobic Gram-Positive Cocci	
Characteristics: Occur singly or in pairs, chains, or clumps.	
Anaerococcus hydrogenalis	*Peptostreptococcus hydrogenalis*
Anaerococcus lactolyticus	*Peptostreptococcus lactolyticus*
Anaerococcus murdochii	
Anaerococcus octavius	*Peptostreptococcus octavius*
Anaerococcus prevotii	*Peptostreptococcus prevotii*
Anaerococcus tetradius	*Peptostreptococcus tetradius*
Anaerococcus vaginalis	
Blautica productus	*Peptostreptococcus productus*
Blautica wexlerae	
Fingoldia magna	*Ruminococcus productus*
Parvimonas micra	*Peptococcus magnus*
	Peptostreptococcus micros
	Micromonas micros
Peptococcus niger	*Micrococcus niger*
Peptoniphilus asaccharolyticus	*Peptostreptococcus asaccharolyticus*
Peptoniphilus gorbachii	
Peptoniphilus harei	*Peptostreptococcus harei*
Peptoniphilus indolicus	
Peptoniphilus ivorii	*Peptostreptococcus ivorii*
Peptoniphilus lacrimalis	*Peptostreptococcus lacrimalis*
Peptoniphilus olsenii	
Peptostreptococcus anaerobius	
Peptostreptococcus indolicus	*Peptococcus indolicus*
Peptostreptococcus magnus	*Peptococcus magnus*
	Peptococcus variabilis
Peptostreptococcus massiliae	
Peptostreptococcus stomatis	
Peptostreptococcus trisimilis	
Ruminococcus faecis	
Ruminococcus gauvreauii	*Streptococcus hansenii*
Slackia heliotrinireducens corrig	*Peptostreptococcus heliotrinireducens*
III. Aerobic Gram-Negative Coccii	
Characteristics: Occur singly or in pairs or clumps; catalase and oxidase positive.	
Lautropia mirabilis	*Sarcina mirabilis*
Neisseria bacilliformis	
Neisseria canis	
Neisseria cinerea	*Micrococcus cinereus*
	Neisseria pharyngis
Neisseria elongata subspecies *elongata*	*Neisseria elongata*
Neisseria elongata subspecies *glycolytica*	*Neisseria elongata*
Neisseria elongata subspecies *nitroreducens*	*Neisseria elongata*
	CDC group M-6
Neisseria flavescens	
Neisseria gonorrhoeae	
Neisseria lactamica	*Neisseria lactamicus*
Neisseria meningitidis	
Neisseria mucosa	
Neisseria parelongata	
Neisseria polysaccharea	
Neisseria shayeganii	
Neisseria sicca	
Neisseria subflava biovar *flava*	*Neisseria subflava*
Neisseria subflava biovar *perflava*	*Neisseria subflava*
Neisseria subflava biovar *subflava*	*Neisseria subflava*
Neisseria wadsworthii	
Neisseria weaveri	Moraxella sp. M-5
	CDC group M-5
IV. Anaerobic Gram-Negative Cocci	
Characteristics: Occur in pairs or clumps.	
Acidaminococcus fermentans	
Acidaminococcus intestini	
Anaeroglobus geminatus	
Megasphaera elsdenii	*Peptostreptococcus elsdenii*
Megasphaera micronuciformis	
Veillonella atypica	
Veillonella denticariosi	
Veillonella dispar	
Veillonella montpellierensis	
Veillonella parvula	
V. Aerobic Gram-Positive Bacilli	
Characteristics: Rodlike; catalase-negative or catalase-positive; some are acid-fast stain–positive, and some have branching. Only *Bacillus, Brevibacillus,* and *Brevibacterium* spp produce spores.	
Actinomadura latina	
Actinomadura madurae	
Actinomadura pelletieri	
Arcanobacterium bernardiae	*Actinomyces bernardiae*
	CDC coryneform group 2
Arcanobacterium haemolyticum	*Corynebacterium haemolyticum*
Arcanobacterium pyogenes	*Actinomyces pyogenes*
	Corynebacterium pyogenes
Arthrobacter albus	
Arthrobacter cumminsii	
Arthrobacter oxydans	
Bacillus anthracis	

Continued on following page

TABLE 79-1 **Current Bacterial Nomenclature, Taxonomy, and Classification** (Continued)

Current Name	Synonym
Bacillus cereus	
Bacillus circulans	
Bacillus coagulans	
Bacillus firmis	
Bacillus idriensis	
Bacillus infantis	
Bacillus lentus	
Bacillus licheniformis	
Bacillus megaterium	
Bacillus mycoides	
Bacillus pumilus	
Bacillus sphaericus	
Bacillus subtilis	
Bacillus thuringiensis	
Brevibacillus agri	*Bacillus agri*
Brevibacillus brevis	*Bacillus brevis*
Brevibacillus centrosporus	
Brevibacillus laterosporus	*Bacillus laterosporus*
Brevibacillus parabrevis	CDC coryneform groups B-1 and B-3
Brevibacterium casei	
Brevibacterium epidermidis	
Brevibacterium mcbrellneri	
Brevibacterium sanguinis	
Cellulomonas denverensis	CDC coryneform group A-3
Cellulomonas hominis	
Cellulosimicrobium cellulans	*Cellulomonas cellulans*
	Oerskovia xanthineolytica
	CDC coryneform groups A-1 and A-2
Corynebacterium accolens	
Corynebacterium afermentans subspecies *afermentans*	CDC coryneform group ANF-1
Corynebacterium afermentans subspecies *lipophilum*	CDC coryneform group ANF-1
Corynebacterium amycolatum	*Corynebacterium xerosis*
	Corynebacterium minutissimum
	Corynebacterium striatum
	CDC coryneform groups F-2 and I-2
Corynebacterium aquaticum	
Corynebacterium argentoratense	
Corynebacterium atypicum	
Corynebacterium aurimucosum	CDC fermentive coryneform group 4
Corynebacterium auris	*Corynebacterium nigricans*
	CDC coryneform group ANF-1
Corynebacterium bovis	
Corynebacterium canis	
Corynebacterium confusum	
Corynebacterium coyleae	
Corynebacterium diphtheriae	
Corynebacterium durum	
Corynebacterium falsenii	
Corynebacterium freiburgense	
Corynebacteriun freneyi	
Corynebacterium glucuronolyticum	
Corynebacterium hansenii	
Corynebacterium imitans	
Corynebacterium jeikeium	*Corynebacterium* group JK
	CDC coryneform group JK
Corynebacterium kroppenstedtii	
Corynebacterium lipophiloflavum	
Corynebacterium macginleyi	CDC coryneform group G-1
Corynebacterium massiliense	
Corynebacterium matruchotii	*Bacterionema matruchotii*
Corynebacterium minutissimum	
Corynebacterium mucifaciens	
Corynebacterium pilbarense	
Corynebacterium pilosum	
Corynebacterium propinquum	CDC coryneform group ANF-3
Corynebacterium pseudodiphtheriticum	*Corynebacterium hofmannii*
Corynebacterium pseudotuberculosis	
Corynebacterium resistens	
Corynebacterium riegelii	
Corynebacterium sanguinis	
Corynebacterium simulans	
Corynebacterium singulare	
Corynebacterium statienis	
Corynebacterium striatum	
Corynebacterium sundsvallense	*Corynebacterium thomssenii*
	Rothia dentocariosa
Corynebacterium thomssenii	
Corynebacterium timonense	
Corynebacterium tuberculostearicum	
Corynebacterium tuscania	
Corynebacterium ulcerans	
Corynebacterium urealyticum	*Corynebacterium* group D2
	CDC coryneform group D2
Corynebacterium ureicelerivorans	
Corynebacterium xerosis	
Curtobacterium spp	
Dermabacter hominis	CDC fermentative coryneform groups 3 and 5
Dermatophilus congolensis	*Actinomyces congolensis*
Dietzia aurantiaca	
Dietzia cinnamea	
Erysipelothrix rhusiopathiae	*Erysipelothrix insidiosa*
Exiguobacterium acetylicum	*Brevibacterium acetylicum*
Exiguobacterium aurantiacum	*Brevibacterium aurantiacum*
Gardnerella vaginalis	*Haemophilus vaginalis*
	Corynebacterium vaginalis
Gordonia bronchialis	*Rhodococcus bronchialis*
Gordonia polyisoprenivorans	
Gordonia rubropertincta	*Rhodococcus rubiopertincta*

TABLE 79-1 **Current Bacterial Nomenclature, Taxonomy, and Classification** (Continued)

Current Name	Synonym
Gordonia sputi	*Rhodococcus sputi*
	Rhodococcus chubuensis
Gordonia terrae	*Rhodococcus terrae*
Listeria grayi subspecies *grayi*	*Listeria grayi*
Listeria ivanovii subspecies *ivanovii*	*Listeria monocytogenes* serovar 5
Listeria ivanovii subspecies *londoniensis*	
Listeria monocytogenes	
Lysinibacillus massiliensis	*Bacillus massiliensis*
Lysinibacillus sphaericus	
Microbacterium foliorum	
Microbacterium oxydans	
Mycobacterium africanum subtype I	
Mycobacterium africanum subtype II	
Mycobacterium agri	
Mycobacterium aichiense	
Mycobacterium alvei	
Mycobacterium aromaticivorans	
Mycobacterium arosiense	
Mycobacterium arupense	
Mycobacterium asiaticum	
Mycobacterium aurum	
Mycobacterium avium subspecies *avium*	
Mycobacterium avium subspecies *paratuberculosis*	
Mycobacterium barassie	
Mycobacterium boenickei	
Mycobacterium bohemicum	
Mycobacterium botniense	
Mycobacterium bouchedurhonense	
Mycobacterium bovis	
Mycobacterium branderi	
Mycobacterium brumae	
Mycobacterium canariassense	
Mycobacterium caprae	
Mycobacterium celatum	
***Mycobacterium chelonae/ abscessus* group**	
Mycobacterium abscessus subspecies *abscessus*	
Mycobacterium abscessus subspecies *bolletii*	
Mycobacterium chelonae	*Mycobacterium chelonei*
Mycobacterium immunogenum	
Mycobacterium salmoniphilum	
Mycobacterium chimaera	
Mycobacterium chitae	
Mycobacterium chlorophenolicum	
Mycobacterium chubuense	
Mycobacterium colombiense	
Mycobacterium conceptionense	
Mycobacterium confluentis	
Mycobacterium conspicuum	
Mycobacterium cookii	
Mycobacterium cosmeticum	
Mycobacterium crocinum	
Mycobacterium diernhoferi	
Mycobacterium doricum	
Mycobacterium duvalii	
Mycobacterium elephantis	
Mycobacterium europaeum	
Mycobacterium fallax	
Mycobacterium farcinogenes	
Mycobacterium flavescens	
Mycobacterium florentinum	
Mycobacterium fluoranthenivorans	
***Mycobacterium fortuitum* group**	
Mycobacterium boenickei	
Mycobacterium brisbanense	
Mycobacterium fortuitum	
Mycobacterium houstonense	
Mycobacterium neworleansense	
Mycobacterium peregrimum	
Mycobacterium porcinum	
Mycobacterium senegalense	
Mycobacterium septicum	
Mycobacterium setense	
Mycobacterium gastri	
Mycobacterium genavense	
Mycobacterium gordonae	*Mycobacterium aquae*
Mycobacterium haemophilum	
Mycobacterium heckeshornense	
Mycobacterium heidelbergense	
Mycobacterium hiberniae	
Mycobacterium interjectum	
Mycobacterium intermedium	
Mycobacterium intracellulare	
Mycobacterium jacuzzi	
Mycobacterium kansasii	
Mycobacterium kubicae	
Mycobacterium lentiflavum	
Mycobacterium leprae	
Mycobacterium lepraemurium	
***Mycobacterium mageritense/ wolinskyi* group**	
Mycobacterium mageritense	
Mycobacterium wolinskyi	
Mycobacterium malmoense	
Mycobacterium mantenii	*Mycobacterium balnei*
Mycobacterium marinum	
Mycobacterium marseillense	
Mycobacterium microti	
Mycobacterium monacense	
Mycobacterium monteofiorense	
***Mycobacterium mucogenicum* group**	
Mycobacterium aubagnense	
Mycobacterium mucogenicum	
Mycobacterium phocaicum	
Mycobacterium moriokaense

Current Name	Synonym
Propionibacterium acidifaciens	
Propionibacterium acnes	
Propionibacterium avidum	
Propionibacterium granulosum	
Propionibacterium lymphophilum	
Propionibacterium propionicum	*Propionibacterium propionicum*
	Arachnia propionica
	Actinomyces propionicus
Pseudoramibacter alactolyticus	*Eubacterium alactolyticum*
Scardovia inopinata	*Bifidobacterium inopinatum*
	Bifidobacterium dentium
Scardovia wiggsiae	
Shuttleworthia satelles	
Slackia exigua	*Eubacterium exigaum*
Solobacterium moorei	
Varibaculum cambriense	
VII. Anaerobic Gram-Positive Bacilli (Spore-Forming)	
Characteristics: Broad, short bacilli with blunt ends. Most organisms readily produce spores, except *Clostridium perfringens* and *Tissierella praeacuta*.	
Clostridium aldenense	
Clostridium amygdalinum	
Clostridium argentinense	*Clostridium botulinum* group G
	Clostridium subterminale
	Clostridium hastiforme
Clostridium baratii	*Clostridium barati*
	Clostridium paraperfringens
	Clostridium perenne
Clostridium bartlettii	
Clostridium bifermentans	
Clostridium bolteae	
Clostridium botulinum	*Clostridium putrificum*
Clostridium butyricum	*Clostridium pseudotetanicum*
Clostridium cadaveris	
Clostridium carnis	
Clostridium celerecrescens	
Clostridium citroniae	
Clostridium clostridioforme	*Clostridium clostridioforme*
Clostridium cocleatum	
Clostridium difficile	*Clostridium difficilis*
Clostridium disporicum	
Clostridium fallax	*Clostridium pseudofallax*
Clostridium ghonii	*Clostridium ghoni*
Clostridium glycolicum	
Clostridium haemolyticum	*Clostridium novyi*
Clostridium hastiforme	
Clostridium hathewayi	
Clostridium hiranonis	
Clostridium histolyticum	
Clostridium indolis	
Clostridium innocuum	
Clostridium intestinale	
Clostridium irregulare	*Clostridium irregularis*
Clostridium leptum	
Clostridium limosum	CDC group P-1
Clostridium malenominatum	
Clostridium neonatale	
Clostridium novyi	
Clostridium orbiscindens	
Clostridium oroticum	*Zymobacterium oroticum*
Clostridium paraputrificum	
Clostridium perfringens	*Clostridium welchii*
	Welchia perfringens
Clostridium piliforme	*Bacillus piliformis*
Clostridium putrefaciens	
Clostridium putrificum	
Clostridium ramosum	*Eubacterium filamentosum*
	Ramibacterium ramosum
	Actinomyces ramosus
	Eubacterium ramosum
Clostridium scindens	
Clostridium septicum	
Clostridium sordellii	
Clostridium sphenoides	
Clostridium spiroforme	
Clostridium sporogenes	Nontoxigenic *Clostridium botulinum*
Clostridium subterminale	
Clostridium symbiosum	*Fusobacterium symbiosum*
	Fusobacterium biacutus
	Bacteroides symbiosus
Clostridium tertium	
Clostridium tetani	
Filifactor alocis	*Fusobacterium alocis*
Filifactor villosus	*Clostridium villosum*
Tissierella praeacuta	*Bacteroides praeacutus*
	Clostridium hastiforme
VIII. Aerobic Gram-Negative Bacilli: Enterobacteriaceae	
Characteristics: Ferment sugars; are oxidase-negative; most reduce nitrate to nitrite. Diagnostic laboratories may report *Salmonella* serovars by name (e.g., *Salmonella typhi* or *Salmonella* serovar *typhi*).	
Buttiauxella gaviniae	
Buttiauxella noackiae	CDC enteric group 59
Cedecea davisae	CDC enteric group 15
Cedecea lapagei	
Cedecea neteri	
Citrobacter amalonaticus	*Levinea amalonatica*
Citrobacter braakii	*Citrobacter freundii*
Citrobacter farmeri	*Citrobacter amalonaticus* biogroup 1
Citrobacter freundii	*Colobactrum freundii*
Citrobacter gillenii	*Citrobacter genomospecies* 10
	Citrobacter freundii
Citrobacter koseri	*Citrobacter diversus*
	Levinea malonatica
Citrobacter murliniae	*Citrobacter genomospecies* 11
	Citrobacter freundii

TABLE 79-1 **Current Bacterial Nomenclature, Taxonomy, and Classification** (Continued)

Current Name	Synonym
Citrobacter rodentium	*Citrobacter genomospecies* 9
	Citrobacter freundii
Citrobacter sedlakii	*Citrobacter genomospecies* 8
	Citrobacter freundii
Citrobacter werkmanii	*Citrobacter genomospecies* 7
	Citrobacter freundii
Citrobacter youngae	*Citrobacter genomospecies* 5
	Citrobacter freundii
Cronobacter dublinensis subspecies *dublinensis*	
Cronobacter malonaticus	
Cronobacter muytjensii	
Cronobacter sakazakii	*Enterobacter sakazakii*
Cronobacter turicensis	
Edwardsiella hoshinae	
Edwardsiella tarda	
Enterobacter aerogenes	*Aerobacter aerogenes*
Enterobacter agglomerans group	
Enterobacter amnigenus	
Enterobacter asburiae	CDC enteric group 17
Enterobacter cancerogenus	*Enterobacter cancerogenus*
	Erwinia cancerogena
	CDC enteric group 19
Enterobacter cloacae	
Enterobacter cowanii	
Enterobacter agglomerans group	*Enterobacter agglomerans* group
Enterobacter agglomerans group	*Enterobacter agglomerans* group
Enterobacter hormaechei subspecies *oharae*	
Enterobacter hormaechei subspecies *steigerwaltii*	
Enterobacter kobei	
Enterobacter ludwisii	
Erwinia persicinus	
Escherichia albertii	
Escherichia blattae	
Escherichia coli	
Escherichia fergusonii	CDC enteric group 10
Escherichia hermannii	CDC enteric group 11
Escherichia vulneris	CDC enteric group 1
Ewingella americana	CDC enteric group 40
Hafnia alvei	*Enterobacter hafniae*
Klebsiella granulomatis	*Calymmatobacterium granulomatis*
Klebsiella ornithinolytica	*Klebsiella oxytoca* ornithine positive
Klebsiella oxytoca	
Klebsiella pneumoniae subspecies *ozaenae*	*Klebsiella ozaenae*
Klebsiella pneumoniae subspecies *pneumoniae*	*Klebsiella pneumoniae*
Klebsiella pneumoniae subspecies *rhinoscleromatis*	
Kluyvera ascorbata	CDC enteric group 8
Kluyvera cryocrescens	
Kluyvera georgiana	CDC enteric group 36/37
	Kluyvera spp group 3
Kluyvera intermedia	*Enterobacter intermedius*
Leclercia adecarboxylata	*Escherichia adecarboxylata*
	CDC enteric group 41
Leminorella grimontii	CDC enteric group 57
Leminorella richardii	
Moellerella wisconsensis	CDC enteric group 46
Morganella morganii subspecies *morganii*	*Proteus morganii*
Morganella morganii subspecies *sibonii*	*Proteus morganii*
Morganella psychrotolerans	
Pantoea agglomerans	*Enterobacter agglomerans*
Pantoea ananatis	
Pantoea dispersa	
Photorhabdus asymbiotica	
Photorhabdus luminescens subspecies *kleinii*	
Photorhabdus temperate subspecies *stackebrandtii*	
Pragia fontium	
Proteus hauseri	*Proteus vulgaris* biogroup 3
Proteus mirabilis	
Proteus penneri	*Proteus vulgaris* biogroup 1
Proteus vulgaris	*Proteus vulgaris* biogroup 2

TABLE 79-1 **Current Bacterial Nomenclature, Taxonomy, and Classification** (Continued)

Current Name	Synonym
Serratia ficaria	
Serratia fonticola	
Serratia grimesii	
Serratia liquefaciens	*Serratia liquefaciens*
	Enterobacter liquefaciens
Serratia marcescens	
Serratia odorifera	
Serratia plymuthica	
Serratia rubidaea	
Shigella boydii	*Shigella* biogroup C
Shigella dysenteriae	*Shigella* biogroup A
Shigella flexneri	*Shigella* biogroup B
Shigella sonnei	*Shigella* biogroup D
Tatumella ptyseos	CDC group EF-9
Yersinia aldovae	
Yersinia bercovieri	
Yersinia enterocolitica	*Yersinia enterocolitica* biogroup 3b
	Pasteurella enterocolitica
Yersinia frederiksenii	
Yersinia intermedia	
Yersinia kristensenii	
Yersinia mollaretii	*Yersinia enterocolitica* biogroup 3a
Yersinia pestis	*Pasteurella pestis*
Yersinia pseudotuberculosis	*Pasteurella pseudotuberculosis*
Yersinia rohdei	
Yersinia ruckeri	
Yokenella regensburgei	*Koserella trabulsii*
	CDC enteric group 45
IX. Aerobic Gram-Negative Bacilli: Nonenterobacteriaceae; Fermentative	
Characteristics: Ferment sugars; are oxidase positive.	
Aeromonas allosaccharophila	
Aeromonas caviae	
Aeromonas enteropelogenes	
Aeromonas hydrophila subspecies *dhakensis*	*Pseudomonas hydrophila*
Aeromonas hydrophila subspecies *hydrophila*	
Aeromonas jandaei	
Aeromonas popoffii	
Aeromonas salmonicida	
Aeromonas schubertii	
Aeromonas tecta	
Aeromonas trota	
Aeromonas veronii biotype *haemolyticum*	
Aeromonas veronii biotype *sobria*	
Aeromonas veronii biotype veronii	
Chromobacterium violaceum	*Bacillus violaceus*
Grimontia hollisae	*Vibrio hollisae*
Pasteurella aerogenes	
Pasteurella bettyae	CDC group HB-5
Pasteurella canis	*Pasteurella multocida* biotype 6
Pasteurella dagmatis	*Pasteurella* new sp 1
	Pasteurella "gas"
Pasteurella gallinarum	
Pasteurella multocida subspecies *gallicida*	
Pasteurella multocida subspecies *multocida*	
Pasteurella multocida subspecies *septica*	*Pasteurella septica*
Pasteurella pneumotropica	
Pasteurella stomatis	
Photobacterium damselae	
Plesiomonas shigelloides	*Aeromonas shigelloides*
Vibrio alginolyticus	*Vibrio parahaemolyticus* biotype 2
Vibrio carchariae	
Vibrio cholerae	*Vibrio comma*
Vibrio cincinnatiensis	
Vibrio damsela	CDC group EF-5
Vibrio fluvialis	CDC group EF-6
Vibrio furnissii	*Vibrio fluvialis* biogroup 2
Vibrio metschnikovii	CDC enteric group 16
	Vibrio cholerae biovar *proteus*
Vibrio mimicus	*Vibrio cholerae* sucrose negative
Vibrio parahaemolyticus	
Vibrio vulnificus	CDC group EF-3
	Beneckea vulnifica
X. Aerobic Gram-Negative Bacilli: Nonenterobacteriaceae; Nonfermentative	
Characteristics: May or may not oxidize sugars; are catalase positive; are oxidase variable.	
Achromobacter denitrificans	*Alcaligenes denitrificans*
	Alcaligenes xylosoxidans subspecies *denitrificans*
Achromobacter insolitus	
Achromobacter piechaudii	*Alcaligenes piechaudii*
Achromobacter spanius	
Achromobacter xylosoxidans	*Alcaligenes xylosoxidans*
	Alcaligenes xylosoxidans subspecies *xylosoxidans*
	Alcaligenes denitrificans subspecies *xylosoxidans*
	Achromobacter xylosoxidans
	CDC groups IIIa and IIIb
Acidovorax delafieldii	*Pseudomonas delafieldii*
Acidovorax facilis	*Pseudomonas facilis*
Acidovorax temperans	*Pseudomonas temperans*
Acinetobacter baumannii	*Acinetobacter anitratus*
Acinetobacter beijerinckii	
Acinetobacter bereziniae	
Acinetobacter calcoaceticus	*Acinetobacter anitratus*
	Acinetobacter calcoaceticus subspecies *calcoaceticus*
Acinetobacter guillouiae	

TABLE 79-1 **Current Bacterial Nomenclature, Taxonomy, and Classification** (Continued)

Current Name	Synonym
Acinetobacter gyllenbergii	
Acinetobacter haemolyticus	*Acinetobacter anitratus*
Acinetobacter johnsonii	
Acinetobacter junii	*Acinetobacter anitratus*
	Acinetobacter grimontii
Acinetobacter lwoffii	*Acinetobacter calcoaceticus* subspecies *lwoffi*
Acinetobacter nosocomialis	*Acinetobacter* genomic species 13TU
Acinetobacter parvus	
Acinetobacter pittii	*Acinetobacter* genomic species 3
Acinetobacter radioresistens	
Acinetobacter schindleri	
Acinetobacter ursingii	
Acinetobacter venetianus	
Advenella incenata	
Agrobacterium radiobacter	*Agrobacterium tumefaciens*
	CDC group Vd-3
Alcaligenes aquatilis	
Alcaligenes faecalis subspecies *faecalis*	*Alcaligenes odorans*
	Pseudomonas odorans
	CDC group VI
Asaia bogorensis	
Azospirillum brasilense	*Roseomonas fauriae*
Balneatrix alpica	
Bergeyella zoohelcum	*Weeksella zoohelcum*
	CDC group IIj
Brevundimonas diminuta	*Pseudomonas diminuta*
	CDC group Ia
Brevundimonas vesicularis	*Pseudomonas vesicularis*
	Corynebacterium vesiculare
Burkholderia ambifaria	
Burkholderia anthina	
Burkholderia arboris	
Burkholderia cenocepacia	
Burkholderia cepacia	*Pseudomonas cepacia*
	Pseudomonas multivorans
	Pseudomonas kingae
	CDC group EO-1
Burkholderia contaminians	
Burkholderia diffusa	
Burkholderia dolosa	
Burkholderia gladioli	*Pseudomonas gladioli*
	Pseudomonas marginata
Burkholderia lata	
Burkholderia latens	*Pseudomonas mallei*
Burkholderia mallei	
	Actinobacillus mallei
Burkholderia metallica	
Burkholderia multivorans	*Burkholderia cepacia* genomovar II
Burkholderia oklahomensis	
Burkholderia pseudomallei	*Pseudomonas pseudomallei*
Burkholderia pyrrocinia	
Burkholderia seminalis	
Burkholderia stabilis	*Burkholderia cepacia* genomovar IV
Burkholderia thailandensis	
Burkholderia ubonensis	*Burkholderia cepacia* genomovar V
Burkholderia vietnamiensis	
Chryseobacterium anthropic	
Chryseobacterium caeni	
Chryseobacterium gleum	*Flavobacterium gleum*
Chryseobacterium hominis	
Chryseobacterium indologenes	*Flavobacterium indologenes*
Chryseobacterium massiliae	CDC group IIb
Comamonas aquatic	
Comamonas kerstersii	CDC group EF-19
Comamonas terrigena	
Comamonas testosteroni	*Pseudomonas testosteroni*
Delftia acidovorans	*Comamonas acidovorans*
	Pseudomonas acidovorans
Elizabethkingia meningoseptica	*Chryseobacterium meningosepticum*
	Flavobacterium meningosepticum
	CDC group IIa
Elizabethkingia miricola	*Chryseobacterium miricola*
Empedobacter brevis	*Flavobacterium breve*
Granulibacter bethesdensis	
Inquilinus limosus	
Kerstersia gyiorum	
Laribacter hongkongensis	
Massilia oculi	
Massilia timonae	
Methylobacterium aminovarans	
Methylobacterium extorquens	
Methylobacterium fujisawaense	
Methylobacterium mesophilicum	
Methylobacterium organophilum	
Methylobacterium podarium	
Methylobacterium radiotolerans	
Methylobacterium rhodesianum	
Methylobacterium rhodinum	
Methylobacterium zatmanii	
Moraxella atlantae	CDC group M-3
Moraxella catarrhalis	*Branhamella catarrhalis*
	Neisseria catarrhalis
Moraxella lacunata	*Moraxella liquefaciens*
Moraxella lincolnii	
Moraxella nonliquefaciens	
Moraxella osloensis	
Myroides odoratimimus	
Myroides odoratus	
Chryseobacterium odoratum	*Flavobacterium odoratum*
	CDC group M-4f

Continued on following page

TABLE 79-1 **Current Bacterial Nomenclature, Taxonomy, and Classification** (Continued)

Current Name	Synonym
Ochrobactrum anthropi	*Achromobacter* spp. biotypes 1 and 2
	CDC groups Vd-1, Vd-2
Ochrobactrum intermedium	
Oligella ureolytica	CDC group Ive
Oligella urethralis	*Moraxella urethralis*
	CDC group M-4
Pandoraea apista	
Pandoraea norimbergensis	
Pandoraea pnomenusa	
Pandoraea pulmonicola	
Pandoraea sputorum	
Paracoccus yeei	*Paracoccus yeeii*
	CDC group EO-2
Photorhabdus asymbiotica	*Xenorhabdus luminescens*
Pseudomonas aeruginosa	*Pseudomonas pyocyanea*
	Bacterium aeruginosum
Pseudomonas alcaligenes	
Pseudomonas chlororaphis	*Pseudomonas aureofaciens*
Pseudomonas fluorescens	
Pseudomonas luteola	*Chryseomonas luteola*
	CDC group Ve-1
Pseudomonas mendocina	CDC group Vb-2
Pseudomonas monteilii	
Pseudomonas mosselii	
Pseudomonas oryzihabitans	*Flavimonas oryzihabitans*
	CDC group Ve-2
Pseudomonas otitidis	
Pseudomonas pseudoalcaligenes	*Pseudomonas alcaligenes* biotype B
Pseudomonas putida	
Pseudomonas stutzeri	CDC group Vb-1
Psychrobacter faecalis	*Micrococcus cryophilus*
Psychrobacter immobilis	
Psychrobacter phenylpyruvicus	*Moraxella phenylpyruvicus*
	CDC group M-2
Psychrobacter pulmonis	
Ralstonia mannitolilytica	
Ralstonia pickettii	*Burkholderia pickettii*
	Pseudomonas pickettii
	CDC groups Va-1, Va-2, Va-3
	Pseudomonas thomasii
Rhizobium radiobacter	*Agrobacterium radiobacter*
Roseomonas cervicalis	CDC "pink coccoid" group
Roseomonas genomospecies 4	CDC "pink coccoid" group
Roseomonas genomospecies 5	CDC "pink coccoid" group
Roseomonas gilardii subspecies *gilardii*	
Roseomonas gilardii subspecies *rosea*	
Roseomonas mucosa	
Shewanella algae	
Shewanella putrefaciens	*Alteromonas putrefaciens*
	Pseudomonas putrefaciens
	CDC groups Ib-1, Ib-2
Sphingobacterium mizutaii	*Flavobacterium mizutaii*
Sphingobacterium multivorum	*Flavobacterium multivorum*
	CDC group IIk-2
Sphingobacterium spiritivorum	*Flavobacterium spiritivorum*
	Sphingobacterium versatilis
	CDC group IIk-3
Sphingomonas parapaucimobilis	
Sphingomonas paucimobilis	*Pseudomonas paucimobilis*
	CDC group IIk-1
Stenotrophomonas maltophilia	*Xanthomonas maltophilia*
	Pseudomonas maltophilia
	Stenotrophomonas africana
Wautersiella falsenii	
Weeksella virosa	*Flavobacterium genitale*
	CDC group IIf
XI. Anaerobic Gram-Negative Bacilli	
Characteristics: May appear as rods with rounded ends, curved rods, coccobacilli, or slender, spindle-shaped rods with tapered ends. *Dialister* and *Johnsonella* belong to the Clostridium subphylum.	
Alistipes finegoldii	
Alistipes indistinctus	
Alistipes onderdonkii	
Alistipes shahii	
Anaerobiospirillum succiniciproducens	
Anaerobiospirillum thomasii	
Anaerorhabdus furcosus	*Bacteroides furcosus*
Anaerostipes cocae	
Bacteroides caccae	
Bacteroides capillosus	
Bacteroides cellulosilyticus	
Bacteroides clarus	
Bacteroides coagulans	
Bacteroides coprophilus	
Bacteroides dorei	
Bacteroides faecis	
Bacteroides finegoldii	
Bacteroides fluxus	
Bacteroides forsythus	
Bacteroides fragilis	
Bacteroides fragilis group	True Bacteroides
Bacteroides intestinalis	*Bacteroides putredinis*
	Alistipes putredinis
	Bacteroides furcosus
Bacteroides massiliae	
Bacteroides nordii	
Bacteroides oleiciplenus	
Bacteroides ovatus	
Bacteroides putredinis	
Bacteroides pyogenes	*Bacteroides tectus*
	Bacteroides tectum
Bacteroides salyersae	*Baceroides suis*
Bacteroides splanchnicus	

TABLE 79-1 **Current Bacterial Nomenclature, Taxonomy, and Classification** (Continued)

Current Name	Synonym	Current Name	Synonym
Bacteroides stercoris		*Parabacteroides goldsteinii*	*Bacteroides goldsteinii*
Bacteroides thetaiotaomicron	*Bacteroides corrodens*	*Parabacteroides gordonii*

TABLE 79-1 **Current Bacterial Nomenclature, Taxonomy, and Classification** (Continued)

Current Name	Synonym
Prevotella loescheii	*Bacteroides loescheii*
Prevotella maculosa	
Prevotella marshii	
Prevotella massiliensis	
Prevotella melaninogenica	*Bacteroides melaninogenicus*
	Bacteroides melaninogenicus subspecies *melaninogenicus*
Prevotella micans	*Prevotella intermedia*
Prevotella multiformis	
Prevotella multisaccharivorax	
Prevotella nanceiensis	
Prevotella nigrescens	
Prevotella oralis	*Bacteroides oralis*
Prevotella oris	*Bacteroides oris*
	Bacteroides ruminicola subspecies *brevis*
Prevotella oulorum	*Bacteroides oulorum*
	Prevotella oulora
Prevotella pallens	
Prevotella pleuritidis	
Prevotella saccharolytica	
Prevotella salivae	
Prevotella scopos	
Prevotella shahii	
Prevotella stercorea	
Prevotella tannerae	
Prevotella timonensis	
Prevotella veroralis	*Bacteroides veroralis*
Prevotella zoogleoformans	*Bacteroides zoogleoformans*
Pyramidobacter piscolens	
Selenomonas artemidis	
Selenomonas dianae	
Selenomonas flueggei	
Selenomonas infelix	
Selenomonas noxia	
Selenomonas sputigena	
Sneathia sanguinegens	*Leptotrichia sanguinegens*
Sutterella parvirubra	
Sutterella wadsworthensis	
Synergistes cluster I	
Synergistes cluster II	
Tannerella forsythia	*Bacteroides forsythus*
	Tannerella forsythensis
XII. Aerobic Gram-Negative Fastidious Coccobacilli	
Characteristics: Small, curved or straight gram-negative bacilli or coccobacilli. They may require carbon dioxide and enriched media or special conditions for adequate growth.	
Actinobacillus equuii	
Actinobacillus hominis	
Actinobacillus lignieresii	
Actinobacillus suis	
Actinobacillus ureae	*Pasteurella ureae*
Afipia broomeae	
Afipia clevelandensis	
Afipia felis	
Aggregatibacter actinomycetemcomitans	*Actinobacillus actinomycetemcomitans*
	CDC groups HB-3, HB-4
Aggregatibacter aphrophilus	*Haemophilus aphrophilus*
	CDC group HB-2
Aggregatibacter paraphrophilus	*Haemophilus paraphrophilus*
Aggregatibacter segnis	*Haemophilus segnis*
Anaplasma phagocytophilum	*Ehrlichia egui*
Arcobacter butzleri	*Ehrlichia phagocytophila* HGE agent
	Campylobacter butzleri
Arcobacter cryaerophilus	*Campylobacter cryaerophila*
Arcobacter skirrowii	
Bartonella alsatica	
Bartonella bacilliformis	
Bartonella bovis	
Bartonella clarridgeiae	
Bartonella doshiae	
Bartonella elizabethae	*Rochalimaea elizabethae*
Bartonella grahamii	
Bartonella henselae	*Rochalimaea henselae*
Bartonella koehlerae	
Bartonella quintana	*Rochalimaea quintana*
Bartonella vinsonii subspecies *arupensis*	*Rochalimaea vinsonii*
Bartonella vinsonii subspecies *berkhoffii*	
Bartonella shoenbuchensis	
Bordetella avium	CDC group IVa
Bordetella bronchiseptica	
Bordetella hinzii	
Bordetella holmesii	CDC group NO-2
Bordetella parapertussis	
Bordetella pertussis	
Bordetella petrii	
Bordetella trematum	
Brucella abortus	
Brucella canis	
Brucella melitensis	
Brucella suis

SUBSECTION 1 *GRAM-POSITIVE COCCI*

CHAPTER 80

Staphylococcus aureus Infections (Coagulase-Positive Staphylococci)

Sheldon L. Kaplan • Kristina G. Hulten • Edward O. Mason

Staphylococcus aureus is a gram-positive coccus that occurs in pairs, chains, and grapelike clusters (Fig. 80-1). *S. aureus* is ubiquitous in nature and can be pathogenic for humans and animals. Staphylococci are nonmotile, are aerobic or facultative anaerobic, and are readily cultivated on routine laboratory media. These organisms are part of the normal human flora. *S. aureus* is responsible for an impressive variety of diseases ranging from minor skin and soft tissue infections to major life-threatening and fatal infections such as bacteremia, endocarditis, pericarditis, pneumonia, empyema, osteomyelitis, myositis, and septic arthritis. The focus of this chapter is on epidemiology, virulence factors, pathogenesis, diagnosis, and treatment of infections caused by *S. aureus*. The reader is referred to the many chapters in this textbook that address the specific infections noted.

On blood agar, *S. aureus* forms round, convex, shiny opaque colonies 1 to 4 mm in diameter, often with a zone of clear β-hemolysis (Fig. 80-2) surrounding the colony. Pigment production is variable, with strains exhibiting a yellow or golden pigment on primary isolation; yellow pigment is actually an *S. aureus* virulence factor.[176] *S. aureus* secretes free coagulase, and this is the basis for the most definitive and most accepted method for identification of pathogenic staphylococci associated with human and animal infection. Free coagulase reacts with coagulase activator in plasma and converts fibrinogen to fibrin with the formation of a fibrin clot. Coagulase also can be evaluated by testing for bound coagulase or clumping factor in a rapid slide test (Fig. 80-3). Clumping factor bound to the organism acts directly on fibrinogen and converts it to fibrin; it is detected by visible clumping or agglutination when a suspension is incubated with plasma. The bound coagulase test is used commonly in clinical laboratories and is more rapid than the tube coagulase test. However, the slide test for clumping factor may be falsely negative in 10 to 15 percent of cases. Thus, a negative slide coagulase test with an isolate that is highly suggestive of being *S. aureus* should be confirmed with a tube coagulase test for free coagulase.[162,234] A limited number of biochemical reactions can differentiate *S. aureus* from other staphylococci (Table 80-1). Commercially available molecular techniques can rapidly detect *S. aureus* from blood cultures with gram-positive cocci in clusters. By including gene targets both for an *S. aureus*–specific gene and a sequence near the insertion site of the staphylococcal cassette chromosome *mec* element (SCC*mec*) in the assay, it is possible to detect *S. aureus* and distinguish methicillin-susceptible (MSSA) isolates from methicillin-resistant (MRSA) isolates simultaneously. If and how the rapid detection of *S. aureus* using these molecular tests impact patient care needs to be determined.[90]

STRUCTURE

Capsule

Capsule production often is considered a virulence factor and frequently is used by bacteria to hinder phagocytosis by the host.[214] Karakawa and colleagues described a scheme of 8 *S. aureus* capsular types in 1982.[148] Subsequently, Sompolinsky and associates described 3 more serotypes, bringing the total number to 11.[265] Most *S. aureus* organisms are encapsulated to a varying degree (Fig. 80-4). Two serotypes (1 and 2) produce mucoid colonies on agar media but are rare among clinical isolates.[265] Serotypes 5 and 8 account for about 75 percent of strains recovered from infections in humans, including children.[56,244,274] In practice, strains that do not belong to serotypes 1, 2, 5, or 8 are referred to as *nontypeable* (see pulsotypes, later).[123] The role of capsule polysaccharide in virulence comes primarily from studies of CP5 and CP8 and is not completely clear. These studies show that inhibition of phagocytosis by capsule can result in persistence on surfaces but modulates adherence to endothelial surfaces.[214] A protein conjugate vaccine composed of CP5 and CP8 conjugated to nontoxic recombinant *Pseudomonas aeruginosa* exotoxin A (StaphVax) initially appeared

promising in prevention of *S. aureus* bacteremia in hemodialysis patients.[257] However, in a larger study this vaccine was not found to be efficacious.[258] The major clone of MRSA associated with community-onset infections, USA300, does not express a capsular polysaccharide, further casting doubt on the contribution of the capsule to virulence of the organism.[274]

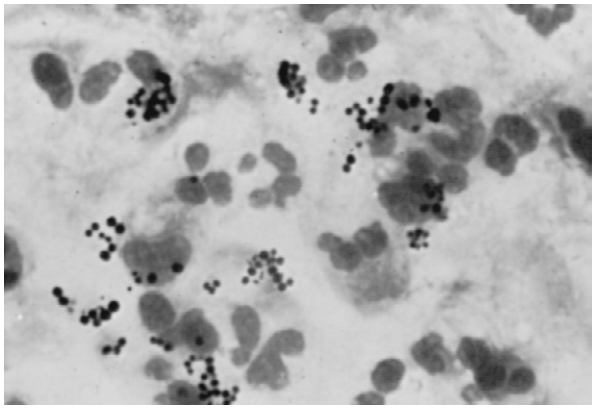

FIGURE 80-1 ■ Staphylococci in pus. The organisms tend to form clusters, are round, and stain purple with Gram stain (positive), similar to bunches of grapes.

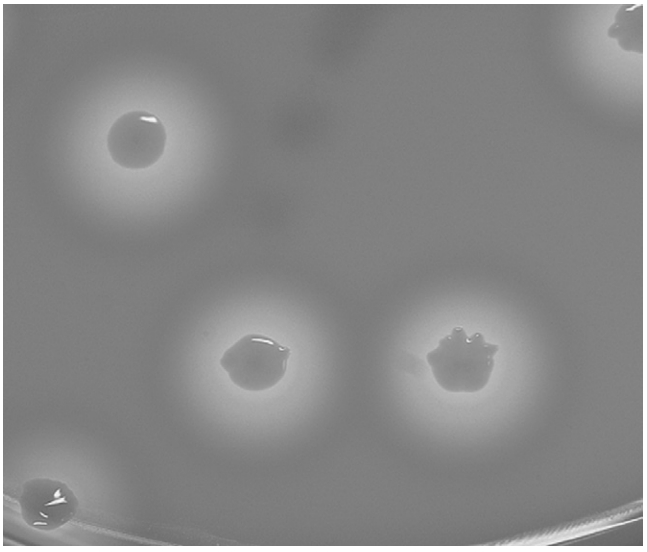

FIGURE 80-2 ■ Typical hemolysis produced by *Staphylococcus aureus* on sheep blood agar.

Protein A

Staphylococcal protein A, a major component of the cell wall of coagulase-positive staphylococci, has been found to bind to the Fc portion of immunoglobulin (Ig) G (IgG). This binding is nonimmune. It differs from specific antigen-antibody reactions in that the reaction is nonspecific, although both precipitation and agglutination are observed. Protein A binds the IgG of many mammalian species. This property has rendered protein A a major reagent in many immune assays. Protein A has also been found to bind to platelets through the platelet gC1qr, a 33-kDa cell protein,[212] as well as to von Willebrand factor,[114] both of which may be important in the pathogenesis of endovascular infections caused by *S. aureus*. Protein A plays a central role in the pathogenesis of staphylococcal pneumonia in that TNFR1, a receptor for tumor necrosis factor-α, is also receptor for protein A, and thus protein A is a principal staphylococcal proinflammatory factor in the lung.[99,222] The complex interactions of protein A, as well as other virulence factors, and the host in the pathogenesis of *S. aureus* pneumonia was reviewed by Parker and Prince.[222] The gene encoding for protein A, *spa*, contains a polymorphic repeat region, which is the target for *spa* typing, a molecular method frequently used to characterize *S. aureus*.[256]

Extracellular Products

S. aureus elaborates a wide variety of extracellular toxins, many of which have potent biologic effects in the isolated

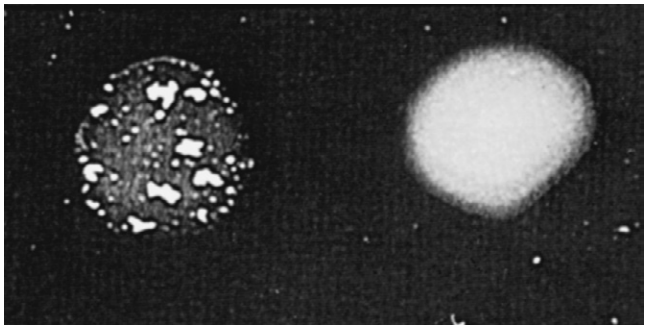

FIGURE 80-3 ■ Bound (slide) coagulase test. A suspension of organisms is mixed with plasma. Immediate clumping (reaction on the *left*) indicates both the presence of bound coagulase and the fact that the organism is coagulase-positive.

state on intact animals, tissues, cells, and membranes. These toxins generally are thought to be responsible for the virulence of *S. aureus*, and the role of several of these products in staphylococcal infections has been proved definitively in humans. The important staphylococcal extracellular products include α-, β-, γ- and δ-hemolysins, coagulases, leukocidin, hyaluronidase, staphylokinase, bacteriocins, the epidermolytic toxins, toxic shock syndrome toxin type 1 (TSST-1), and the enterotoxins. In recent years a group of cytolytic peptides, the phenol-soluble modulins, have gained attention for their moderate cytolytic capacity, although the precise function of these molecules remains unclear.[156] The pore-forming toxins include α hemolysin, γ hemolysin, Panton-Valentine leukocidin (PVL), LukED, and LukAB (also referred to as LukGH).[66,288]

Almost half of the known toxins and virulence genes in *S. aureus* are found in pathogenicity islands. These genetic clusters, commonly of 15 to 20 kb, also contain genetic elements such as integrases and transposases. A high genetic instability is associated with many of these islands, and mosaic structures are common findings. Seven pathogenicity islands (νSa) have been associated with *S. aureus*.[93] Table 80-2 lists some of the features described for these islands, although allelic variations in gene content occur. All sequenced strains of *S. aureus* contain variations of the νSaα, νSaβ, and νSaγ.[60,93,124] In addition to the pathogenicity islands, virulence genes are also located on prophages (e.g., *luk*S-PV and *luk*F-PV on ΦSa2).

Hemolysins and Leukocidins

Encoded by *hla*, α hemolysin is produced by most *S. aureus* isolates and is a classic pore-forming bacterial toxin. The purified toxin has impressive hemolytic, dermonecrotic, and lethal properties. Advances in protein purification have allowed the production of pure toxin; this development, in turn, has led to a better understanding of its properties.

The protein interacts with and damages a variety of cell membranes, releases hemoglobin from erythrocytes of various mammalian and avian species, and is cytotoxic to a number of cell lines in tissue culture. It lyses rabbit and human platelets and disrupts lysosomes. It causes contraction in skeletal and vascular smooth muscle, with the latter action perhaps explaining its property of causing localized dermal necrosis. In a rat model, α toxin damaged the air-blood barrier in vivo during *S. aureus* pneumonia.[193] The α toxin forms pores in the membranes of endothelial cells, leading to vasoconstriction and increasing vascular permeability, and also has effects that lead to apoptosis of a number of different cells.[62] Damage from the α toxin to endothelial cells is mediated via its binding to the receptor for A-disintegrin and metalloprotease 10 (ADAM10).[229] This toxin also is an important activator of caspase 1/calpain signaling, which leads to pyroptosis, a form of inflammatory death, of human keratinocytes in vitro, which may allow *S. aureus* to penetrate across the skin to cause infection.[266]

Injection of α toxin is lethal to mammals and reptiles, with death occurring within 2 to 5 minutes. Human death has been attributed to preformed α toxin on at least one occasion. Anti–α toxin can be demonstrated in normal individuals,[47] and antibody to α hemolysin was protective in a mouse model of *S. aureus* pneumonia.[237] However, because the level of anti–α hemolysin is high in approximately 70 percent of patients with staphylococcal osteomyelitis and the antibody is also present in children with acute osteomyelitis at the time of admission to hospital, there is doubt regarding a protective role, at least in patients with osteomyelitis.[39,276]

The other hemolytic toxins, γ, β, and δ hemolysin, also possess hemolytic and cytotoxic activities. Highly cytotoxic, γ hemolysin lyses human neutrophils; and β toxin produces lethal and dermonecrotic effects. Eighty to 100 percent of adults possess antibody to β hemolysin. LukAB/GH has a reduced cytolytic action on neutrophils compared with γ hemolysin and PVL.[66] The biologic role of LukED remains unknown, although a variant of this molecule was highly toxic against human neutrophils.[206]

Despite evidence that these toxins are produced during infection, their roles in production of the typical staphylococcal tissue lesion remain unclear.[22,62] Although the toxins may play important roles in the establishment of infection by interacting with each other and with other biologically active staphylococcal products, this theory has not been proven; human infection is not prevented by antitoxin antibody, and virulent staphylococci that lack one or more of these toxins are encountered.[263]

An in vitro study showed that α toxin was present in culture supernatants at sevenfold to ninefold greater concentrations in the USA300 strain compared with the USA400 strain when grown at midexponential and stationary phases of growth.[34] Further studies on how the strain-specific expression of virulence factors during the establishment and course of infection influence the pathology and host response are warranted.

Even though certain hemolysins are toxic to various leukocytes, PVL is the only known extracellular toxin that attacks the leukocyte exclusively.[221] It consists of two protein components, LukS-PV and LukF-PV, encoded by the genes *lukS-PV* and *lukF-PV* carried on a bacteriophage. LukS-PV and LukF-PV assemble to form octameric β-barrel pores in polymorphonuclear leukocytes and macrophages.[27] Leukocidin injected into rabbits causes a striking fall in levels of circulating and bone marrow leukocytes, followed by marked granulocytosis; these changes occur without death of the rabbits. Leukocidin interacts with the membrane phospholipid and causes depolarization, increased permeability, and cell death. Local secretion of leukocidin might appear to confer an advantage to the staphylococcus by killing leukocytes and thereby preventing phagocytosis and intracellular killing. Levels of anti-leukocidin rise rapidly in the course of infection,[96,135] and some evidence indicates that infants and mothers with high levels of anti-leukocidin antibody are less likely to contract staphylococcal disease in high-risk epidemiologic situations.[18] In one study, a history of furunculosis, suggesting a skin infection caused by PVL-producing *S. aureus* isolates, was associated with a decrease in complications and mortality for patients with *S. aureus* PVL-associated necrotizing pneumonia.[238] Brown and colleagues noted that children who had invasive staphylococcal infections such as osteomyelitis or pneumonia had higher antibody concentrations to PVL at the time of admission to the hospital than children with skin and soft tissue infections, suggesting that PVL antibodies were not protective against invasive *S. aureus* infections.[30] Similarly, high levels of PVL antibody were not found to prevent initial or recurrent skin community-acquired methicillin-resistant *S. aureus* (CA-MRSA) infections.[117]

In early studies, only a fraction of *S. aureus* isolates recovered from humans carried the PVL genes.[230] Interest in PVL greatly increased after reports that *S. aureus* isolates carrying PVL genes were associated with severe furunculosis[51] and particularly necrotizing pneumonia in children and adolescents that frequently was fatal.[72,95,170] Furthermore, the independent emergence worldwide of CA-MRSA clones that generally carry the PVL genes led to further studies of the role of PVL in the pathogenesis of *S. aureus* infections.[286] The USA300 CA-MRSA clone has been especially linked to PVL[202,204] Using polymerase chain reaction (PCR) the PVL genes have been increasingly detected (*pvl*$^+$) in CA-MSSA strains in the United States as well.[31,127] In children with invasive *S. aureus* osteomyelitis, the presence of the PVL genes has been associated with greater local and systemic inflammation, longer extent of fever, greater frequency of positive blood cultures, and more frequent complications such as the development of chronic osteomyelitis or venous thrombosis.[25,63,189] Pulmonary manifestations were also more frequently observed among children with invasive *S. aureus* infections caused by *pvl*$^+$ isolates[100]; *pvl*$^+$ strains were isolated almost exclusively among a group of children with staphylococcal pneumonia in one study.[36] In adults with staphylococcal pneumonia, *pvl*$^+$ isolates were associated with increased rates of mortality in one study but were not found to a significant factor in a larger study of hospital-acquired or ventilator-associated pneumonia.[182,225] In a multicenter international study, *pvl*$^+$ did not

predict outcome of *S. aureus* skin and soft tissue infections in adults.[282] Thus, the presence of PVL genes may be a marker for isolates capable of causing more severe disease in some populations of patients but not in others.[73]

The role of PVL in the pathogenesis of infection in experimental models also remains controversial. The contribution of PVL to severity of *S. aureus* infections has been examined in mice using isogenic *pvl*$^+$ or *pvl*$^-$ isolates. One study found no difference in lethality for sepsis or abscess volume in a skin abscess model,[291] as well as no difference in the destruction of human neutrophils by the isogenic strains. The investigators concluded that PVL was not a major virulence determinant of CA-MRSA. The other study found *pvl*$^+$ isolates caused much greater lung inflammation and necrosis in a mouse acute pneumonia model.[160] PVL was detected in the infected lung tissues. These investigators also discovered that staphylococcal protein A is more highly expressed in *pvl*$^+$ strains and postulated that PVL coupled with increased staphylococcal protein A could result in greater tissue inflammation than what is found with *pvl*$^-$ strains. A clear role for PVL has been shown in the pathogenesis of necrotizing pneumonia and necrotizing skin infections in a rabbit model.[59,174] In a rabbit model of osteomyelitis using an isogenic PVL genes negative derivative of a USA300 CA-MRSA isolate (LAC), PVL appeared to play a role in the persistence and extension of infection.[50] The discrepancy in these studies may be explained by use of different *S. aureus* isolates as well as different models of infection, especially the differential activity of PVL on neutrophils from humans or rabbits compared with murine or simian cells.[181]

Although the exact role of PVL in *S. aureus* infections has not been fully established, treatment measures directed against PVL have been proposed. These measures include the preferred use of protein-inhibiting antibiotics rather than, or in addition to, bactericidal antibiotics to decrease PVL production,[65,269] as well as adjunctive administration of intravenous immunoglobulin (IVIG) preparations containing PVL antibody.[92] However, currently there is no evidence that neutralizing PVL or decreasing PVL production affects outcomes.

Enzymes

Staphylococci elaborate a variety of enzymes, including hyaluronidase, nuclease, proteases, lipase, catalase, lysozyme, and lactate dehydrogenase, that might play a role in the spread of infection in local tissues or the establishment of a nidus of infection.

Other biologically active extracellular products, as yet unidentified, undoubtedly are produced by the staphylococcus. The potency and number of these weapons in the armamentarium of the coagulase-positive staphylococcus, in contrast to the small number of extracellular products associated with the much less virulent coagulase-negative staphylococcus, suggest that the synergistic action of these toxins and enzymes may explain the superior ability of coagulase-positive staphylococci to establish infection and cause tissue necrosis. Several extracellular toxins have been proved to have specific roles in staphylococcal infection or disease: the epidermolytic toxins, TSST-1, and the enterotoxins.

Epidermolytic Toxins

Two biochemically and immunologically distinct exotoxins, epidermolytic toxins A and B (epidermolysins, exfoliatins), can separate adjacent cell layers within the epidermis and cause the various skin manifestations of the staphylococcal scalded skin syndrome (SSSS). The toxin acts extracellularly and does not induce cell death directly or lysis of the cell membrane or elicit an inflammatory response. It does not damage any organ or cell, except those of the upper epidermis.[69] These low-molecular-weight (~24,000 daltons) protein exotoxins are now known to hydrolyze desmoglein-1, an important structural skin protein.[10] Exfoliatin toxin D has been associated with bullous impetigo but not SSSS.[256,305]

Toxic Shock Syndrome Toxin Type 1

TSST-1 was discovered independently in 1981 by two research groups. It was documented to be an excellent marker for staphylococci associated with vaginal toxic shock syndrome (TSS), in which it correctly identified more than 90 percent of strains in blinded testing. In experimental animal models, purified TSST-1 can induce the major physiologic changes of TSS: fever, mucous membrane suffusion, renal impairment, hepatic damage, hypocalcemia, lymphocytopenia, and hypotension. TSST-1 can be detected in blood, pus, urine, and tissues during human and experimental model TSS. USA300, the major CA-MRSA clone in the United States, does not carry the gene encoding TSST-1.[204] Toxic shock syndrome and the role of TSST-1 as a superantigen are discussed in Chapter 64.

Enterotoxins

Over 20 different staphylococcal enterotoxins (SEA to SE*l*V) have been identified, most of which cause emesis in primates.[62,116] The toxins are heat stable and resist boiling. Therefore, once sufficient toxin has formed within food, even heating or boiling will not inactivate the toxin. Foods involved in outbreaks of food poisoning frequently have been inoculated by a lesion on the hand of a food handler in situations in which the food is then held at temperatures that allow bacterial growth (between 25° and 60° C) for some time before the food is served. Foods implicated in particular are ham, salads with starch and mayonnaise, salami, poultry, cream sauces, pastries, and dairy products. The mode of action of enterotoxins is not well understood in part because of the lack of a convenient animal model.[185] Intravenous injection of purified enterotoxins in laboratory animals causes hypotension, cardiovascular collapse, and death. The significance of these properties of enterotoxins in naturally occurring human infections is unknown, although they may be linked to clinical syndromes, including TSS. Enterotoxin A often is elaborated with TSST-1 in menstrual-associated TSS, but it also is elaborated

without TSST-1 in patients with septicemia in whom TSS does not develop. Staphylococcal enterotoxin B, most often isolated in phage group V organisms, is associated with local infections and pneumonia.[188] USA300 strains typically do not contain the genes encoding most enterotoxins but frequently contain molecular variants of enterotoxins Q and K.[58] In contrast, USA400 isolates may carry many of the enterotoxin genes, including enterotoxin H, which is unique among the other *S. aureus* genomes.[14,210]

Staphylococcus aureus Microbial Surface Components Recognizing Adhesive Matrix Molecules

Bacterial adherence to host tissues is mediated by a number of bacterial surface components or adhesins that recognize and bind to host extracellular matrix and cell surface molecules.[134] The subfamily of adhesins that bind to the extracellular matrix are known as microbial surface components recognizing adhesive matrix molecules (MSCRAMMs). For *S. aureus*, important MSCRAMMs are protein A, fibronectin-binding proteins (A and B), clumping factors A and B (fibrinogen-binding proteins), and collagen-binding protein (Cna).[81] Many other less well-characterized adhesins also have been identified from the *S. aureus* genome.[243] The MSCRAMMs are linked to bacterial wall peptidoglycan after sortase cleavage of the LPXTG (LeuProXThrGly) motif that is a conserved C-terminal cell wall sorting signal among the adhesins.[42] Fibronectin-binding proteins play a role in *S. aureus* invasion into endothelial cells.[25,134] Collagen adhesin protein may contribute to the pathogenesis of *S. aureus* musculoskeletal infections,[68,219] although there are conflicting animal studies as well as clinical studies in this area.[136,248] USA300 CA-MRSA isolates do not carry the Cna gene, *cna*, yet osteomyelitis and septic arthritis are common CA-MRSA invasive infections in children.[35,189]

Clumping factor A has been the target for protective immunity in the prevention of *S. aureus* infections, and this approach has been successful in experimental models.[289] The safety and pharmacokinetics of an intravenous immunoglobulin preparation enriched for antibody to clumping factor A were established in low-birth-weight infants; however, a large randomized trial did not document efficacy in prevention of staphylococcal infections in this population.[24] A monoclonal antibody (tefibazumab [Aurexis]) directed against clumping factor A has undergone preliminary evaluation as adjunctive therapy for *S. aureus* bacteremia in adults, but further development of the product is doubtful.[296]

Regulation

Bacterial pathogenesis is reliant on cell population, density-dependent gene expression. This quorum sensing acts to adjust the production of accessory genes (e.g., virulence genes), depending on the needs of the cell. Studies have shown that in low-density populations, when the bacterial cells are multiplying, accessory genes are either turned off or expressed at a low level to the advantage of other genes, such as genes involved in cell wall formation. In high-density bacterial populations, expression of the accessory genes is increased. The accessory gene regulator, *agr*, is genus specific, and the effector molecule is a regulatory RNA molecule, named RNAIII. Many staphylococcal toxins and virulence factors are under the regulation of *agr*, and *agr* dysfunction is associated with reduced clearance of MRSA infection by vancomycin.[2,13,29,84,203] The staphylococcal accessory regulator, sar*A*, is another global regulator in *S. aureus*. The *sar* locus produces three overlapping transcriptional units (*sarB*, *sarC*, and *sarA*), and the effector peptide, SarA, is a DNA-binding protein that functions as a transcriptional regulator. In animal models of infection, both RNAIII and SarA have been shown to affect virulence. In addition to *agr* and *sar*A, several other factors have been described that affect accessory gene regulation.[23] Thus, the complex network of regulatory operons that act on each other and/or directly on specific genes is not completely understood.

Staphylococcal L-Forms and Small Colony Variants

L-forms are staphylococcal variants with impaired or absent cell walls. L-forms can be induced in vitro by growing staphylococci in hypertonic media, in the presence of the muralytic enzyme lysostaphin, or with the addition of antibiotics that inhibit the formation of cell walls, such as the penicillin-methicillin group, cycloserine, and vancomycin. These L-forms, or protoplasts, require hypertonic environments for survival, do not accept Gram stain, and are resistant to cell wall–inhibiting antibiotics. Under favorable conditions, L-forms revert to complete bacteria with cell walls.

Clinical interest in L-forms has arisen because of concern that antibiotics might induce these forms in vivo. L-forms then could persist in the host in a latent or less virulent phase and revert to a fully virulent state at some time when antibiotics no longer are present. Identification of L-forms in specimens from human infection or in infected animals treated with antibiotics has been reported exceedingly rarely, despite considerable effort.[293] Despite extensive laboratory and clinical investigation, no evidence has demonstrated that L-forms are important causes of bacterial persistence in clinical infections.

Small colony variants of *S. aureus* are isolates with atypical colony morphology, decreased hemolysis and pigmentation, decreased growth rate, and unusual biochemical characteristics that result in difficulty isolating and identifying these organisms.[287] Small colony variants also have been implicated in persistent and recurrent *S. aureus* infections, including osteomyelitis,[232] brain abscesses, and pulmonary infections in patients with cystic fibrosis.[141,254] Small colony variants can persist intracellularly, are often more resistant to antibiotics than the parent strain and antibiotics that penetrate into cells (e.g., rifampin), and do not activate innate host systems to the same degree as wild-type phenotypes, which helps to explain their successful intracellular persistence.[233,283]

Staphylococcal Cassette Chromosome *mec*

The staphylococcal cassette chromosome mec (SCC*mec*) is a region spanning between 20 and 70 kb located approximately 30 kb downstream of the chromosomal origin of replication. SCC*mec* contains the *mec*A gene encoding a penicillin-binding protein (PBP2a or 2′) with poor affinity to β-lactam antibiotics, allowing essential functions of cell wall formation to proceed in the presence of β-lactam antibiotics. The *mec*A gene is regulated by *mecR1* and *mec*I where activated *mec*R1 (signal transducer) inactivates *mec*I (repressor) through site-specific proteolytic cleavage, thereby initiating production of PBP2′. In vitro studies have suggested that the β-lactamase regulators *bla*R1 and *bla*I may also be effective regulators of *mec*A.[196]

The SCC*mec* classification systems are based on several genetic elements including the class of *mec* and the *ccr* genes, which are recombination genes involved in the mobility of the genetic cassette. Other elements that may be present are IS431, IS1272, Tn554, pUB110, and pT181. SCC*mec* types II and III also contain other antibiotic resistance genes such as *tet* (tetracycline resistance). All strains contain a J(unk) region of variable size and composition. Several schemes for SCC*mec* typing have been published.[154,216,217] Historically, nosocomial MRSA isolates contained the SCC*mec* types I to III; and when community isolates were first described, three new types—IV, V, and VI—were introduced. Two more SCC*mec* types have been described, tentatively named VII and VIII. The smaller size (<30 kb) of SCC*mec* IV to VI is thought to explain an increased mobility between strains. Because the community strains have been brought into the health care setting, SCC*mec* typing cannot be used to predict whether an infection is health care or community related.[102,115,255]

TYPING METHODS

Staphylococcal strains were historically characterized by bacteriophage typing (World Health Organization method).[19] *S. aureus* isolates are susceptible to lysis when exposed to bacteriophages. Bacteriophage typing has been used primarily as an epidemiologic tool for identifying related strains in epidemics. An international system for strain identification by bacteriophage typing has been established but is not widely used. Staphylococci of phage group 80/81 were widespread during the pandemic of staphylococcal disease in the late 1950s. At present, a wide variety of phage types are involved in staphylococcal disease.[242]

In the 1990s pulsed-field gel electrophoresis (PFGE) became the gold standard for strain typing utilized by both reference and research laboratories.[277] The method is reliable and reproducible, and the use of digital imaging and band analysis has enhanced the quality of inter-gel comparisons. The Centers for Disease Control and Prevention (CDC) used the PFGE method to define and interrelate *S. aureus* clones and designated 11 staphylococcal clones circulating in the United States as USA100 to USA1100.[192*]

Multilocus sequence typing (MLST) is a nucleotide sequence-based method adapted from multilocus enzyme electrophoresis (MLEE). In MLST typing the alleles at each locus of seven housekeeping genes (*arc*C, *aro*E, *glp*F, *gmk*, *pta*, *tpi*, and *yqi*L) are determined through PCR amplification, nucleotide sequencing, and submission of sequence data via computer website to the MLST database (http://www.mlst.net).[70] In this database, strains can be compared with strains submitted by other investigators and within-laboratory comparisons with control strains thus have become obsolete.

spa typing is a single-locus sequence method, based on the polymorphic X or the short sequence repeat (SSR) region of the protein A gene.[260] *spa* typing has some advantages over PFGE in terms of speed, interpretation, and exportability, the main limitation being the single-locus–based design.[110] Less commonly used methods include repetitive-element PCR (rep-PCR), restriction fragment length polymorphism (RFLP), and toxin typing.

Staphylococcus aureus Clones in the Hospital and in the Community

Of the methods mentioned earlier, MLST has been especially useful in dividing *S. aureus* strains into lineages (or clonal clusters). Frequently, these clones are described in the literature by their sequence type followed by the SCC*mec* type (e.g., ST8-IV). Most human *S. aureus* strains belong to 1 of 10 independent lineages. Five major clonal clusters (CC) that have been described to contain a majority of the human MRSA strains are CC5, CC8, CC22, CC30, and CC45. Of these, MRSA clones within the CC5 and CC8 clusters have been recognized as the main causes of hospital outbreaks worldwide.[46] Examples of widespread hospital MRSA clones are EMRSA15-ST22, EMRSA16 (ST36-II), the Archaic (ST250-I or 247-I), the Pediatric (ST5-IV), and the Brazilian (ST239-III) clones.[98]

Although a few hospital MRSA clones have circulated around the world, genetically distinct community clones have been reported from different geographic areas. Commonly, these strains contain the smaller SCC*mec* elements, type IV or V.[241] Why these different clones emerged in parallel at this point in time is unknown.

In the United States, the two most commonly described community MRSA clones are USA300-ST8 and USA400-ST1. USA400, originally described as MRSA strain MW2 which caused four pediatric deaths in Minnesota and North Dakota, was more commonly observed in the midwestern states.[89] USA300 is the most frequently reported strain causing community-acquired disease in both pediatric and adult settings in the United States.[56] Like many other epidemic strains, it has been associated with a spectrum of disease presentations ranging from simple skin and soft tissue infections[142,146] to severe sepsis syndrome,[101] sometimes with fatal outcome. USA300 is a highly virulent strain that has been distributed over the

*Available through the Network on Antimicrobial Resistance of *Staphylococcus aureus* (NARSA) at http://www.narsa.net.

continent and has become the most prevalent cause of community-acquired and community-onset health care–associated infections in less than a decade in the United States as well as in many other countries on different continents.[125,204,213] It has also become the most common source of hospital-acquired *S. aureus* infection in many hospitals, where it has acquired one or more antibiotic resistance markers.[57,102,126,255]

MLST typing has enabled the ancestry of many of these clones to be traced phylogenetically. For example, phage type 80/81 (ST30-MSSA) was epidemic in the 1960s and is the likely ancestor to the widely circulated Southwest Pacific clone ST30-MRSA-IV, which has been successful both as a colonizer and as a cause of diseases ranging from skin and soft tissue infections to invasive manifestations.[242] Similarly, the USA300 (ST8-MRSA-IV) clone is postulated to have descended from an archaic ST8-MSSA.[71]

GENOMES

The list of current or completed *S. aureus* genome sequencing projects, submitted to the National Institute of Health (NIH) genomes database (www.ncbi.nlm.nih.gov) contains more than a hundred isolates and is continuously increasing. The sequenced genomes include representatives of the widespread CA-MRSA clones from the United States (e.g., MW2[14], FPR3757,[60] and TCH 1516[120]). Among the sequenced hospital-associated MRSA strains, one of the first reported MRSA clones, *S. aureus* COL,[93] as well as EMRSA-16,[137] N315, and Mu50,[159] have been sequenced. In addition, methicillin-susceptible isolates such as strains 476[124] and NCTC 8325[94] have been well defined.

Genome sizes range from 2.7 to 3.1 Mb, and the structures of the chromosomes are conserved. The core genome (the part of the genome that is the same in all strains) represents approximately 75 percent of the genome.[171] The biologic function remains unknown for at least a third of the predicted proteins. In the future the knowledge gained from these ongoing sequencing projects and analyses of the resulting large datasets will provide a deeper insight into the genetic differences of *S. aureus* strains and may give clues into the strain-specific causes of disease versus colonization, suggest candidate genes for potential vaccine or drug targets, or provide information into the acquisition of antibiotic resistance or virulence factors. For example, a comparative genome project of vancomycin-resistant strains provided proof that the vancomycin-resistant isolates reported to date in the United States all represented new acquisition of transposon Tn1546 from *Enterococcus* spp. and also identified a change in a gene important for uptake of foreign DNA, which may have facilitated the genetic exchange.[155]

EPIDEMIOLOGY

S. aureus isolates are responsible for both sporadic infections and epidemics of varying extent ranging from the intrafamily outbreaks of staphylococcal disease commonly encountered to large and often prolonged hospital-associated outbreaks, such as those emanating from a neonatal nursery or a surgical service. Epidemic spread of staphylococci of phage type 80/81 was so widespread worldwide in the period encompassing the mid 1950s through the early 1960s that it constituted a pandemic. Researchers have suggested that a few "epidemiologically virulent" strains, such as 80/81, are particularly capable of spreading widely and causing disease. Robinson and colleagues[242] concluded that descendants of 80/81 have acquired methicillin resistance to emerge as a CA-MRSA clone, closely related to the southwest Pacific ST30 clone. Because we are largely ignorant of the factors responsible for pandemic spread, we cannot prevent or predict recurrence.

Staphylococci may be transmitted by multiple routes, including contact with infected persons, contact with asymptomatic carriers, airborne spread, and contact with contaminated objects. Of these mechanisms, contact with a person who has a staphylococcal lesion appears to be particularly important in the spread of staphylococci. Persons with open draining lesions disseminate organisms into their environment and to others via direct contact. In a hospital, staphylococci may be spread from an infected patient to another on the hands of caretakers, such as physicians or nurses. Hospital personnel with mild or unapparent lesions, such as sties, furuncles, or paronychia, may themselves spread organisms. In family and small community outbreaks, multiple secondary cases can occur and frequently can be traced to an individual with a draining lesion. Secondary cases tend to appear for months after the initiating case within these small epidemiologic units.[267] Staphylococci also may be spread by asymptomatic carriers who have staphylococci in one or more body sites, including the nose, skin, hair, nails, axillae, and perineum.

At any one time, up to 30 percent of individuals are colonized in their anterior nose with *S. aureus*.[152] The rate of nasal carriage of MRSA appears to have increased. Nasal carriage of MRSA was 0.8 percent in 2001[211] and 9 percent in 2004[49] for children seen in an emergency center in Nashville, Tennessee. For children admitted to a hospital in Corpus Christi, Texas, in 2005, the rate of MRSA colonization was 22 percent.[7] In 2004 to 2005, an average of 2.6 percent (range, 0% to 9%) of children in 11 different practices in the St. Louis metropolitan area was colonized with MRSA in the nose.[86] Why nasal colonization of children by CA-MRSA has increased over the past decade is unclear but is likely related to unique properties of the major CA-MRSA clone USA300.[60] Actually for children with skin and soft tissue infections, CA-MRSA colonization of the groin is more commonly detected than is nasal carriage.[88]

Detailed studies have been performed to delineate factors regulating the carrier state and its establishment and perpetuation, as well as factors responsible for dispersion of organisms from carriers. Asymptomatic carriers may be a source of disease for themselves and others. For example, a wound infection appears to be more likely to develop in a hospitalized patient who becomes a carrier

than in a noncarrier.[297] Much attention has been devoted to detecting and attempting to treat nasal carriers of staphylococci; however, studies of nursery outbreaks have indicated that nasal carriage is not as important as is hand transmission in the dispersal of staphylococci.[298] Transmission by hand contact can be minimized by effective hand washing.[97] The problem of hair carriage of staphylococci in operating room personnel has been minimized by using improved head coverings.

Staphylococci are widespread in the environment and can be cultured from clothing, carpets, toiletries (e.g., hairbrushes, razors), and virtually all environmental surfaces. Airborne dissemination of organisms is possible, particularly in operating rooms with poor ventilation and heavy traffic; improved methods of ventilating operating rooms may have reduced the sepsis or colonization rate. Environmental staphylococci may serve as an important reservoir, but direct human-to-human transfer probably is a much more important means of transmission in epidemic situations than is airborne spread or contact with contaminated objects. This means of transmission is particularly true for spread of CA-MRSA among athletes.[150] Furthermore, USA300 appears to be especially able to spread among household members, in part related to increased contamination of environmental surfaces.[200,284] Molecular methods of typing offer adjunctive information useful in characterizing strains involved in outbreaks.[61,70]

The neonatal nursery has been an area of particular concern in the transmission of *S. aureus*. During the pandemic of strain 80/81 disease, outbreaks of serious neonatal disease were commonplace, high colonization rates were found in infants on discharge from the nursery, and the subsequent incidence of disease in some outbreaks was as high as 50 to 70 percent. Skin disease and infant and maternal mastitis usually appear within 1 to 4 weeks after discharge. Staphylococcal pneumonia, far more common during that period than at present, may not be seen for months after delivery, even though the infecting strain was acquired in a hospital. During the experience with strain 80/81 disease, a particularly high staphylococcal attack rate was seen in the families of colonized infants. The same epidemiology has been noted for the USA300 CA-MRSA clone that has been associated with staphylococcal infections in otherwise healthy newborns up through 30 days of life.[79] One study reported that 20 percent of infants with a *S. aureus* infection had a mother with a concomitant (proven or presumed) infection.[79] In a study of infants up to 30 days of age with community-onset *S. aureus* infections, the infecting strain in the neonate was the same as a nasal *S. aureus* strain recovered from the mother in 8/34 (24%) mother-neonate pairs.[78] This suggests that maternal nasal colonization is not the sole source of *S. aureus* isolates causing infection in their otherwise healthy full-term neonate. In other studies, *S. aureus* colonization of infants was more likely to be related to horizontal than vertical transmission from the mother.[132]

Various control measures were used successfully to terminate individual outbreaks during the 1980s. Measures to protect the infant from colonization and subsequent development of disease by establishing a barrier at the site of initial colonization included hexachlorophene bathing, application of antibiotic ointment to the umbilicus and circumcision site, and application of an antiseptic dye to the umbilicus. Another approach, deliberate colonization of the umbilicus with an interfering "avirulent" strain, was successful in controlling several epidemics but itself has caused skin disease and, in one case, fatal septicemia.[259] Hexachlorophene bathing became a widespread practice during the period in which nosocomial staphylococcal infections were declining.[97,227] After approximately a decade of using hexachlorophene, researchers recognized that cutaneous absorption of hexachlorophene could result in potentially toxic hexachlorophene blood levels in infants, particularly premature ones, subjected to repeated daily baths over time. Brain stem abnormalities associated with the use of hexachlorophene have been demonstrated in premature infants. For these reasons, controls were placed on the sale of hexachlorophene, and its routine use was discouraged in 1973. In one neonatal nursery outbreak of MRSA, the use of 0.3 percent triclosan (Bacti-Stat) was associated with cessation of an outbreak.[307]

Patterns of crowding of infants and understaffing contribute to outbreaks. Active clinical and bacteriologic surveillance and cohorting of infants may be effective in reducing outbreaks.[16,109]

S. aureus bacteremia related to intravenous catheters and *S. aureus* infections of prosthetic devices are common.[37,186,187] In particular, methicillin-resistant staphylococci are responsible for widespread nosocomial outbreaks of disease in hospitals.*

HOST DEFENSES

S. aureus is ubiquitous in the environment, and approximately 30 percent of the population are carriers. A major defense against staphylococcal infection is intact skin. Minor wounds frequently become colonized and infected and serve as portals to deeper, more significant staphylococcal infection. In some cases, the integumentary infection may be of major importance; in others, minor skin punctures may serve to introduce infection to distant internal sites. Burns, varicella virus and cutaneous herpesvirus infections, insect bites, minor lacerations or abrasions, primary skin diseases (e.g., atopic eczema), epidermolysis bullosa, and surgical wounds are important portals of entry for staphylococci. A deficiency in peptides (defensins and cathelicidins) important for innate immunity of skin against *S. aureus* has been shown in skin specimens from patients with atopic dermatitis and likely contributes to the increased susceptibility of the skin to *S. aureus* infections in these patients.[153,218] In hospitalized patients, intravenous needles and catheters may be sources of staphylococcal infection.[186,187]

Foreign bodies reduce local resistance to staphylococcal engraftment and are important in the pathogenesis and perpetuation of infection. Noteworthy foreign bodies

*References 26, 32, 48, 53, 73, 151, 251, 271, 295.

are cerebrospinal fluid shunts, prosthetic cardiac valves, nonabsorbable sutures, vascular prostheses (including arteriovenous shunts for hemodialysis), orthopedic prostheses, nails, and wires. In neonates, the umbilicus and circumcision sites, which may be colonized within the first few hours of life and from which both local and distant infections may be established, are important portals of entry.

Viral respiratory diseases such as measles and influenza[108,228] predispose to development of pulmonary infection, again predominantly by damaging the integrity of the barrier at the portal of entry. In an animal model, differences in the ability of *S. aureus* strains to cause secondary bacterial pneumonia after influenza can be demonstrated.[129] Disruption of the respiratory epithelium and impairment of ciliary motion and other local defenses may allow secondary staphylococcal invasion.

Once the integumental barrier has been breached, the polymorphonuclear leukocyte appears to be the most important line of defense. Successful phagocytosis involves chemotaxis, opsonization, and intracellular killing. The incidence of difficulty with staphylococcal infection is highest in patients with defects in this area of host defense.[80,126,303] Granulocytopenia of any origin predisposes to the development of infection, particularly with the host's endogenous bacteria, including staphylococci.[15] Krishna and Miller have extensively reviewed the innate and adaptive immune response of the skin to *S. aureus* infections.[157]

Once the staphylococcus and the leukocyte are close to one another, opsonization of the bacterium must proceed for phagocytosis to occur. Two systems for opsonization of staphylococci have been described. Serum from normal adults has good opsonic activity when unheated but is generally inactive after heating at 56° C for 1 hour. The heat lability of normal opsonin and the observation of normal or only slightly decreased opsonic activity in unheated sera from patients with agammaglobulinemia[301] indicate that the major opsonin is complement. A few sera, generally from patients convalescing from serious staphylococcal disease, contain heat-stable opsonins, presumably antibody directed at the staphylococcal cell wall components.[163] Therefore, either complement or antibody can provide opsonins for staphylococci; specific antibody is helpful but not required. The clinical correlate to these observations may be found in patients with defective defenses; patients with agammaglobulinemia and defective antibody generally have more severe problems with organisms other than staphylococci, whereas patients with deficiencies in complement components have been reported to have repeated and severe staphylococcal infections.*

Once the bacterium has been ingested, intracellular killing proceeds normally. Coagulase-positive staphylococci can survive within polymorphonuclear leukocytes for a considerably longer period than can coagulase-negative organisms.[198] Prolonged intracellular survival may be an important virulence factor separating coagulase-negative from coagulase-positive strains and may provide a mechanism whereby surviving organisms may be carried to distant body sites to establish metastatic foci of infection. A number of *S. aureus* exotoxins outlined earlier, such as PVL, contribute to the ability of *S. aureus* to evade human neutrophils. In addition, many *S. aureus* genes are regulated upward or downward after exposure to human neutrophils and there are differences in gene expression among various strains in response to human innate host response that might account for differences in the ability of the isolate to cause infection.[290]

Patients with chronic granulomatous disease of childhood have an inborn error in intraleukocytic killing of catalase-positive bacteria and fungi. These patients have an early onset of recurrent purulent infections of the skin, subcutaneous tissue, lungs, and reticuloendothelial organs, particularly the liver, that often are caused by *S. aureus*.[236] Staphylococcal infections are also characteristics of hyper-IgE syndrome. Neutrophil disorders are discussed in detail in Chapters 2 and 67.

In contrast to the primacy of polymorphonuclear defense against staphylococci, evidence for an important role of specific humoral and cellular immunity in host defense against staphylococci is either lacking or contradictory. Specific antibody is not required for opsonization of unencapsulated strains of staphylococci. The opsonic activity of serum from patients recovering from staphylococcal endocarditis or other serious disease is greater than that of otherwise normal persons.[163,300] Despite the presence of humoral antibodies to cell wall teichoic acids and to various toxins and enzymes, which are found regularly in those convalescing from serious staphylococcal infection, the patient remains susceptible to recurrence of infection with the same strain of staphylococci. Staphylococcal infections generally occur and progress in the presence of some degree of humoral immunity. Specific antibody to one or more staphylococcal components or products does not protect against infection.

Clinical evidence from patients with deficient cell-mediated immunity (combined immunodeficiency, thymic aplasia, Nezelof syndrome) suggests that staphylococcal infections are not among the most important pathogens in these patients. However, in an animal model, interleukin-17 production by local T cells is important for host defense against *S. aureus* cutaneous infections.[45]

Present evidence, therefore, suggests that intact local skin and mucous membrane barriers are the most important defense against the establishment of staphylococcal infection. Once infection is established, an intact polymorphonuclear response is essential for containment of the infection and clearance of the organisms.

Genomic studies are leading to a greater understanding of the host response to *S. aureus* and may lead to novel treatment or prevention modalities. Using microarray techniques to describe the host immune transcriptional profile in children with primarily invasive *S. aureus* infections, Banchereau and colleagues[17] found an overexpression of innate immunity and hematopoiesis genes and an underexpression of genes associated with adaptive immunity. Differences in gene expression were seen between children with musculoskeletal infections and those with pneumonia. Of interest, patients with

*References 4, 8, 9, 82, 201, 224.

osteoarticular infections displayed overexpression of transcripts linked to coagulation of blood that might relate to the venous thromboses that may occur with *S. aureus* osteomyelitis.[103]

PATHOGENESIS

Staphylococci cause disease by two mechanisms: direct invasion of tissues with liberation of toxins, which may have effects at sites distant from the focus of infection, and colonization. The hallmark of a staphylococcal lesion is the abscess. Local tissue destruction at the site of inoculation is followed rapidly by hyperemia and a vigorous inflammatory response marked by the accumulation of large numbers of polymorphonuclear leukocytes. Tissue necrosis in the center of the lesion occurs next. At the site of intensive hyperemia surrounding the lesion, a fibrin wall is formed. Liquefaction necrosis occurs centrally; the mature lesion consists of a fibrin wall surrounded by inflamed tissues enclosing a central core of pus consisting of organisms and leukocytes. Live bacteria may persist within these lesions for a considerable period of time. As pus accumulates, it may drain toward the skin surface or into adjacent tissues, where it forms sinus tracts and secondary abscesses. In the presence of an intact host inflammatory response, this type of reaction may be seen in diverse areas, including the skin and subcutaneous tissues, lymph nodes, joints, kidney, liver, parotid glands, muscles, lungs, and long bones.

In addition to local extension, *S. aureus* may disseminate hematogenously from this focus of infection, even from abscesses that are trivial in size. Hematogenous dissemination may result in infection of bones, joints, and heart valves. Given the ubiquitous nature of staphylococci, skin and wounds, which are the usual ports of entry, appear to be remarkably resistant to infection. This natural resistance is affected dramatically by the presence of foreign bodies within the wound, such as sutures and bits of soil or gravel. Natural resistance also is affected by the tissue compromise that occurs after ecchymosis or hemorrhage and by vascular insufficiency. Poor personal hygiene likewise predisposes to development of staphylococcal skin infection. Moist, macerated skin is invaded more easily and thus contributes to the increased frequency of staphylococcal skin infection in intertriginous areas and in tropical climates.

Toxigenic staphylococcal disease includes staphylococcal scalded skin syndrome, TSS, and staphylococcal food poisoning. Toxin can be elaborated from *S. aureus* isolates that are colonizing sites without a specific site of infection but leading to TSS. The major manifestations of these diseases are caused by the effects of specific toxins. Clinical manifestations of infections caused by *S. aureus* in children are discussed in multiple chapters, and the reader is referred to the specific infection of interest.

DIAGNOSIS

The diagnosis of significant staphylococcal infections should be pursued with vigor. Collections of pus, whether superficial or deep, should be aspirated or drained surgically for diagnostic and therapeutic purposes. Gram stain and culture should be performed. An aggressive approach to the diagnosis of osteomyelitis by bone aspiration and bone biopsy provides an etiologic security that is helpful during the prolonged treatment phase that necessarily follows. When infection is associated with a foreign body, such as an intravenous catheter or suture, removal and culture of the foreign body help in determining the etiology and removal is almost always required for successful resolution of infection.

When possible, at least two blood cultures should be obtained before starting therapy for all serious infections. One need not wait for fever spikes or delay therapy to obtain specimens. Blood cultures frequently are negative in serious staphylococcal infection, a fact that demonstrates the need for performing other cultures. Blood cultures are positive in most cases of staphylococcal endocarditis, approximately half the cases of osteomyelitis and septic arthritis, and less than half the cases of pneumonia and deep tissue abscesses. A number of molecular tests are available to rapidly identify MRSA once isolated (or growing in blood culture bottles) in the microbiology laboratory as well as to detect MRSA colonization in patients at the time of hospital admission.[285]

Measurement of nonspecific indicators of inflammation (e.g., erythrocyte sedimentation rate and C-reactive protein), although of limited value in diagnosis, can be helpful in monitoring the clinical course of infection and response to intervention. Accurate, sensitive serologic methods for making a diagnosis of serious staphylococcal infection are not available.

Enterotoxins can be identified by a variety of methods. Immunoassay is used routinely but may lack the sensitivity required to detect levels seen in staphylococcal food poisoning. DNA oligonucleotide probes are highly sensitive, but their clinical utility is limited by the identification of nonexpressed genes.[215]

TREATMENT

Successful treatment of staphylococcal infection depends on adequate drainage of collections of pus and the rational use of antibiotic therapy. Strategies for clinical management of MRSA infections, including those in children, are outlined in guidelines published by the Infectious Diseases Society of America.[175] Staphylococcal infections have a particular tendency to persist and recur; for these reasons, prolonged antibiotic therapy usually is required for all but minor infections. Surgical drainage is extremely important and, in some patients with minor superficial abscesses, may be all that is required.[44,67] In one study an abscess less than 5 cm in diameter was associated with successful outcome after incision and drainage regardless of whether the antibiotic administered was active against the isolated pathogen, which was CA-MRSA.[167] In other studies the size of the abscess was not associated with outcome.[45] But for some infections, a period of antibiotic therapy after surgical drainage better ensures that the infection has been contained. In an adult study, antibiotics active against CA-MRSA were associated with

significantly greater cures than agents not active against CA-MRSA in patients who had undergone incision and drainage of skin and soft tissue infections.[246] Failure to provide surgical drainage is an important reason for persistence or recurrence of organisms. Antibiotics cannot be expected to penetrate into the avascular center of abscess cavities. When abscess cavities are undrained or when antibiotic therapy is discontinued before an area is sterilized, live bacteria may persist and disseminate to cause later recurrence at that site or distant sites. After incision and drainage, adjunctive antibiotics are recommended for patients with underlying conditions or with immunosuppression; multiple sites of infection; rapidly progressive lesions or lesions associated with cellulitis; abscesses located on the face, hand, or perineum; young children (<1 to 2 years old); or those patients whose condition has not improved with incision and drainage alone.[175]

For moderate to severe staphylococcal infection, the patient should be hospitalized initially for intravenous therapy. This strategy ensures peak antibiotic levels, which may allow greater penetration into relatively avascular areas. Once the patient is afebrile, has a negative blood culture, and there is definite evidence of clinical improvement, therapy can be completed with home administration of antibiotics or with oral agents, as deemed appropriate by the treating physicians.

Antibiotics for *Staphylococcus aureus* Infections

Since the mid 1960s, the vast majority of *S. aureus* isolates from most sections of North America and Europe have been penicillinase producers and, therefore, penicillin resistant. When *S. aureus* is likely to be the cause of infection, the most appropriate agents to administer for empirical treatment of infections with onset in the community in normal children are based on the relative frequency of CA-MRSA isolates in the particular community. In areas where CA-MRSA isolates are not a concern, treatment with a penicillinase-resistant penicillin or cephalosporin should be initiated before isolation of bacteria and susceptibility testing (Tables 80-3 and 80-4). Methicillin-resistant organisms cannot be treated

TABLE 80-3 **Therapy for Staphylococcal infections in Infants and Children (Excluding Neonates)**

Drug	*Oral (Mild–Moderate Infection)*		*Parenteral (Moderate–Severe Infection)*	
	CHILDREN <40 KG	CHILDREN >40 KG AND ADULTS	CHILDREN <40 KG	CHILDREN >40 KG AND ADULTS
Penicillins				
Oxacillin			150-200 mg/kg/24 hr in 4-6 doses q4–6hr IV	4-8 g/24 hr in 4-6 doses q4–6hr IV
Nafcillin			150-200 mg/kg/24 hr in 4-6 doses q4–6hr IV	4-8 g/24 hr in 4-6 doses q4–6hr IV
Cloxacillin	50-100 mg/kg/24 hr in 4 doses	2-4 g/24 hr in 4 doses		
Dicloxacillin	25-75 mg/kg/24 hr in 4 doses	1-2 g/24 hr in 4 doses		
Cephalosporins				
Cefazolin (Ancef, Kefzol)			75-100 mg/kg/24 hr in 3 doses q8hr	4-6 g/24 hr in 3 doses
Cephalexin (Keflex)	25-100 mg/kg/24 hr in 4 doses	1-4 g/24 hr in 4 doses		
Cefadroxil (Duricef, Ultracef)	30 mg/kg/24 hr in 2 doses	1-2 g/24 hr in 2 doses		
Other Agents				
Erythromycin	35-50 mg/kg/24 hr in 4 doses	1-2 g/24 hr in 4 doses		
Clindamycin	25-40 mg/kg/24 hr in 3 doses	600-1200 mg/24 hr in 3-4 doses	30-40 mg/kg/24 hr q6–8h IV	600-3000 mg/24 hr q6–8h IV
Vancomycin			40-60 mg/kg/24 hr q6h drip over 1 hr or by continuous IV drip	1-2 g/24 hr q6h over 1 hr or by drip continuous drip
Linezolid	10 mg/kg/dose q8hr*	10 mg/kg/dose q12hr†	10 mg/kg/dose q8hr*	10 mg/kg/dose q12hr†
Doxycycline	2-4 mg/kg/24 hr 1or 2 doses for children >7 yr of age	100-200 mg/24 hr		
Trimethoprim-sulfamethoxazole	8-12 mg/kg/24 hr of TMP in 2 doses	160 mg of TMP q12hr		

*The dose for children younger than 12 years.
†The dose for children ≥ 12 years of age, not to exceed 600 mg/dose.

TABLE 80-4 **Anti-staphylococcal Therapy in Neonates with Moderate to Severe Infection ≤ 28 Postnatal Days of Age**

Drug	*Body Weight <2 kg*		*Body Weight > 2 kg*	
	<1 WEEK	1-4 WEEKS	<1 WEEK	1-4 WEEKS
Oxacillin or Nafcillin IV	25 mg/kg/dose q12hr	25 mg/kg/dose q8hr	25mg/kg/dose q8hr	25 mg/kg/dose q6hr
Linezolid IV	10 mg/kg q12hr	10 mg/kg/dose q8hr	10 mg/kg/dose q8hr	10 mg/kg/dose q8hr
Vancomycin IV	Dose based on serum creatinine*			

*Vancomycin Dose Recommendations (modified from American Academy of Pediatrics. *Red Book: 2012 Report of the Committee on Infectious Diseases*. Pickering LK, ed. 29th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2012.

Creatinine Concentration (mg/dL)†	Vancomycin Dose
<0.7	15 mg/kg q12hr
0.7-0.9	20 mg/kg q24hr
1-1.2	15 mg/kg q24hr
1.3-1.6	10 mg/kg q24hr
>1.6	15 mg/kg q48hr

†Add 0.2 mg to serum creatinine concentrations for these dosing recommendations for neonates ≤ 28 weeks' gestational age.

adequately with β-lactam antibiotics, including cephalosporins. In some locations, methicillin resistance is widespread in community isolates and thus alternative agents (see later) are indicated for empirical treatment. When a penicillin-resistant organism that is susceptible to oxacillin is isolated (MSSA), the semisynthetic penicillinase-resistant penicillins are the drugs of choice. Oxacillin and nafcillin are available for parenteral use. Dicloxacillin and cephalexin are the preferred oral agents.

If clinical response appears to be slow, nothing is to be gained by switching to another antibiotic within the same category; instead, microbiologic data should be reviewed and the dose of antibiotic rechecked to be certain it is correct, the patient is reassessed to be certain all sites requiring drainage have been addressed, and compliance with therapy is assured, especially if the antibiotics have been administered orally.

The cephalosporin antibiotics are active against penicillinase-producing staphylococci and cause less irritation of veins with intravenous infusion than do penicillinase-resistant penicillins. A potential disadvantage lies in their broader spectrum of activity, which may promote superinfection with cephalosporin-resistant, gram-negative organisms in a debilitated patient with serious staphylococcal disease. Cephalosporins have been advocated widely for use in patients allergic to penicillin, but because of considerable cross-reactivity, they should be used extremely cautiously, if at all, in patients with a clear history of serious penicillin allergy or anaphylaxis. Among this group of antibiotics, cefazolin is the agent of choice for parenteral use.[226] It is well tolerated and can be administered every 8 hours intravenously. Serum concentrations of cefazolin are higher, and effective tissue levels appear to be easier to attain. Cefazolin also is associated with less bone marrow suppression than nafcillin or oxacillin. The efficacy of the second- and third-generation cephalosporins against *S. aureus* is reduced. Therefore, these drugs, especially cefotaxime, ceftriaxone, and cefuroxime, should be given in addition to specific antistaphylococcal agents if *S. aureus* is strongly suspected. Clindamycin and trimethoprim-sulfamethoxazole are alternative agents for patients who are seriously allergic to or intolerant of β-lactam antibiotics.[12,74,147] Clindamycin is an important option for treating invasive *S. aureus* infections but should only be considered if or when blood cultures are negative and endovascular infection, such as infective endocarditis, is not a concern because clindamycin is a bacteriostatic agent. In one study using a large insurance database for assessing outcome of large numbers of children with skin and skin structure infections (not *S. aureus*–specific infections), trimethoprim-sulfamethoxazole and cephalexin were more likely than clindamycin to be associated with treatment failures and recurrences.[299]

The β-lactam resistance of MRSA is caused by the production of a novel penicillin-binding protein (PBP) designated PBP-2′, which unlike the intrinsic set of PBPs (PBP-1 to PBP-4) of *S. aureus* has remarkably reduced binding affinities to β-lactam antibiotics. Despite the presence of otherwise inhibitory concentrations of β-lactam antibiotics, MRSA can continue to synthesize cell walls solely through the uninhibited activity of PBP-2′ οr 2α.[149,191] PBP-2′ is encoded by the *mec*A gene, which is carried by a unique mobile genetic element integrated into the *S. aureus* chromosome designated SCC*mec*.[122]

Some cases of MRSA actually may be caused by infection with *S. aureus* that lacks the *mec*A gene responsible for true methicillin resistance. The mechanism of resistance in these cases may be hyperproduction of β-lactamase.[139] Frequently in these cases, methicillin resistance is borderline, with minimal inhibitory concentrations (MICs) of 8 μg/mL or less. The clinical significance of these isolates is unknown.

Management of Methicillin-Resistant *Staphylococcus aureus*

MRSA first was described within 1 year of the introduction of penicillinase-resistant penicillins.[131] Initial reports of infection appeared in England in the early 1960s and

subsequently were followed by reports from other European countries.[161,270] In the United States, only sporadic cases were observed initially[151,161] and not until 1968 was the first nosocomial outbreak described.[20] Since then, the prevalence of MRSA in the hospital setting has increased steadily. In a survey of U.S. hospitals performed in 1989, 97 percent reported the presence of MRSA.[26] The SCOPE prospective surveillance project conducted between 1995 and 2001 identified over 3400 episodes of nosocomial bacteremias in children. *S. aureus* accounted for 9 percent of isolates.[302] The proportion of *S. aureus* isolates that were MRSA increased from 10 percent in 1995 to 29 percent in 2001. Risk factors associated with infection or colonization with MRSA include recent or prolonged hospitalization, exposure to antibiotics, and stay in an intensive care unit.[177] Nosocomially acquired MRSA appears to be fully virulent, with in vitro characteristics similar to those of methicillin-susceptible staphylococci, and equivalent virulence in studies of experimental infection in mice. Clinical studies confirm comparable mortality rates.[119,281] These strains characteristically are multiresistant and usually show little or no susceptibility to cephalosporins, aminoglycosides, erythromycin, clindamycin, and tetracyclines.[5,294] The clinical efficacy of cephalosporins against methicillin-resistant strains has been poor.[294]

Epidemic outbreaks of nosocomially acquired MRSA have been reported. In these outbreaks, nasopharyngeal colonization with MRSA often occurs before infection. A high rate of nasal and hand carriage has been observed in health care workers associated with units that have MRSA outbreaks.[207] The usual approach to outbreaks has been to emphasize hand washing between examining and caring for patients. Strict isolation in a private room generally is advocated.[208] Single-room isolation may be impractical in neonatal and some pediatric intensive care units, where isolation facilities are in short supply and a single MRSA-colonized patient may occupy a room for months. Strict adherence to universal precautions (body substance isolation) with all moist body fluids and strict hand washing between seeing patients appear to be rational alternatives to "strict isolation."[183] Intranasal application of mupirocin ointment has been found to be capable of eliminating nasal and hand carriage of both colonized patients and hospital staff.[240] Interventions to control outbreaks of MRSA in intensive care or other units are multifaceted, and the reader is referred to major guidelines for recommendations.[208,262]

Occasional cases of MRSA infection apparently acquired in the community were observed sporadically in the 1970s. However, these infections were from patients who were chronically ill, and many gave a history of nursing home residence, recent admission to acute or chronic health care facilities, previous receipt of antibiotics, or intravenous drug abuse.[168,195,250,273] Hence, in these cases, infections usually were traceable to the hospital setting. By contrast, since the 1980s, cases of true CA-MRSA infection in patients without identified risk factors have appeared in the literature. The first reports in children arose from small MRSA outbreak investigations.[111] Subsequently, Rathore and Kline described three patients with deep-seated infections caused by MRSA acquired in the community.[239] In the 1990s, reports of CA-MRSA in patients without known risk factors continued to appear sporadically in the literature. However, most of the infections described occurred in adults.[105,164,205] Four pediatric deaths in Minnesota and North Dakota in the period 1997 to 1999 demonstrated the potential for severe disease from CA-MRSA infections.[89] The landmark study describing the changing epidemiology of CA-MRSA in children was published in 1998.[118] Herold and colleagues performed a retrospective review of medical records and compared the frequency of *S. aureus* isolation in hospitalized children during two time periods: between 1988 and 1990 and between 1993 and 1995. The prevalence of CA-MRSA in children without identified risk factors was 25.9 times higher in 1993 to 1995 than in 1988 to 1990.[118] After the publication of this article, several reports of CA-MRSA in children without risk factors from different parts of the United States and many regions of the world have appeared.* This explosive increase in reporting that occurred in just a few years suggests that clones of CA-MRSA have unique properties that allow rapid spread once they are introduced into the community.[143]

All reports of the clinical characteristics of CA-MRSA infection in children without risk factors document a predominance of superficial infections, including subcutaneous abscesses and cellulitis.[31,88,108,175] However, a large proportion of children with abscesses require admission to the hospital for incision and drainage under anesthesia.[146] Recurrent skin infections are also very common. Invasive disease with CA-MRSA, including severe, life-threatening infection, has been increasing and accounted for about 5 percent of cases in children seeking care in an emergency center of a large children's hospital in Houston.[6,89,100,101,146]

Unlike hospital-acquired MRSA, CA-MRSA isolates usually are susceptible to most non–β-lactam antibiotics, including clindamycin, gentamicin, trimethoprim-sulfamethoxazole, and doxycycline or minocycline, in addition to vancomycin, daptomycin, and linezolid.[142] Erythromycin susceptibility is somewhat more variable, with the proportion of susceptible isolates varying from 29 to 80 percent in various studies.[106,118,128,209] Macrolide (erythromycin, azithromycin, clarithromycin)-resistant strains remain susceptible to clindamycin if the macrolide resistance is caused by an efflux pump (MEF). Clindamycin, lincosamide, and streptogramin B resistance can be constitutive (MLS_B) or inducible ($iMLS_B$). Both mechanisms can be detected with molecular methods but can be detected reliably in the routine laboratory by the "D test" (Fig. 80-5).[75] An important note is that in vitro as well as some in vivo evidence indicates that in the presence of erythromycin resistance *S. aureus* could become resistant to clindamycin during therapy with this antibiotic.[64,194,220,292] This phenomenon, inducible macrolide-lincosamide-streptogramin B (MLS_B) resistance, which consists of modification of the target rRNA of *S. aureus*, is mediated by the presence of the resistance-conferring *erm* (erythromycin resistance methylase) gene, which

*References 33, 43, 140, 146, 235, 253, 308.

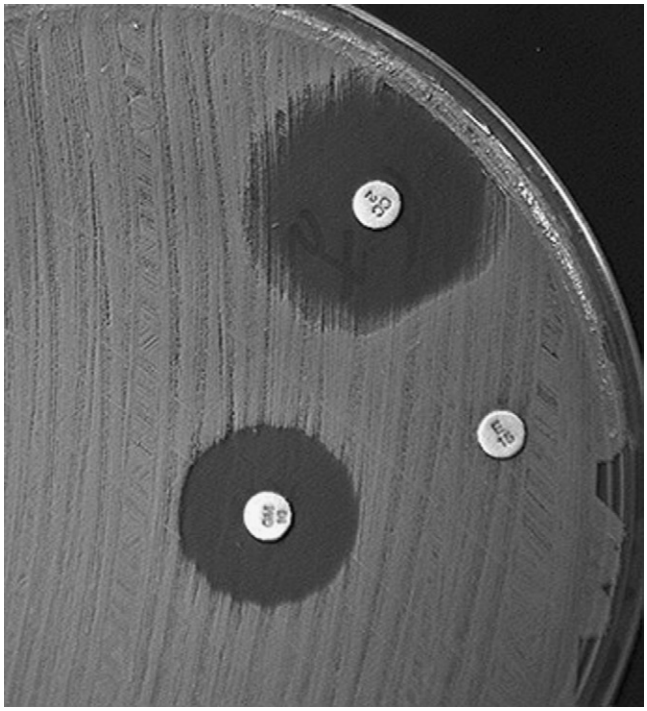

FIGURE 80-5 ■ D test.

encodes a 23S rRNA methylase.[130,165] Although 14-membered ring macrolides such as erythromycin are the most potent inducers, lincosamides such as clindamycin also can act as weaker inducers.[165] This ability may have clinical relevance in the setting of infections for which the bacteria are not eliminated quickly and may be exposed to subinhibitory concentrations of clindamycin for any amount of time. Examples include therapy for undrained deep-seated abscesses or treatment of osteoarticular infections. In patients infected with a strain having the inducible MLS_B resistance genotype and expressing the erythromycin-resistant, clindamycin-susceptible phenotype, cases of clindamycin therapeutic failure have been reported.[85,169,261] Therefore, for MRSA isolates that are erythromycin resistant and clindamycin susceptible, detection of the presence of inducible MLS_B resistance should be performed by the disk approximation method, in which clindamycin- and erythromycin-impregnated disks are set 15 to 20 mm apart over Mueller-Hinton agar containing a standard inoculum of bacteria. After a 24-hour incubation period, if the zone of inhibition around the clindamycin disk is flattened or blunted ("D shaped"; see Fig. 80-5) on the side facing the erythromycin disk, the isolate is classified as having an inducible MLS_B resistance phenotype.[165]

Vancomycin is the drug of choice for serious MRSA infections. There is no evidence that addition of an aminoglycoside or rifampin to vancomycin is beneficial for treatment of infections that do not involve prosthetic material.[223] Linezolid, an oxazolidinone antibiotic, has demonstrated significant activity against MRSA, vancomycin-resistant enterococci, and penicillin-resistant *Streptococcus pneumoniae*. Linezolid is an important option for treatment of MRSA infections due to clindamycin-resistant isolates and may be a drug of choice for treating MRSA pneumonia.[145,304] It is available in both oral and intravenous formulations. Quinupristin-dalfopristin is an intravenous streptogramin antibiotic combination that has been found to be effective in the treatment of MRSA and vancomycin-resistant *Enterococcus faecium* infections in patients intolerant of or failing previous therapy. The frequent development of phlebitis with parenteral administration through a peripheral vein mandates the use of central venous access whenever possible. Both linezolid and quinupristin-dalfopristin are expensive, so their use should be restricted to situations for which other alternatives are not feasible. Quinupristin-dalfopristin has only been studied in children in compassionate use trials, and the development of other agents has limited its use in pediatrics.[180] Daptomycin has rapidly bactericidal activity in vitro against MRSA and is an effective agent for treating MRSA infections, including bacteremia and right-sided endocarditis in adults.[28,83] Pharmacokinetic studies in children indicate a larger dose per kilogram is required to obtain the same drug exposure in adults that resulted in effective treatment of MRSA infections.[1] The safety and efficacy of daptomycin for treating *S. aureus* infections in children are being studied. Ceftaroline is a fifth-generation cephalosporin that is approved for treatment of MRSA skin and soft tissue infections in adults, and studies are being conducted to determine the pharmacokinetics, safety, and efficacy of this agent in children.[252]

For severe infections caused by MRSA, the antibiotic of choice is vancomycin. In areas where CA-MRSA has been isolated from children without identified risk factors, severe, life-threatening infections suspected to be caused by *S. aureus* should be treated empirically with both nafcillin and vancomycin because nafcillin is a more active antibiotic than is vancomycin for the treatment of methicillin-susceptible isolates.[104] Antibiotic therapy can be adjusted subsequently after antibiotic susceptibility testing results are available. Clindamycin and linezolid are options for therapy depending on the susceptibility of the isolate, the desired route of administration, and the absence of endovascular involvement. Daptomycin is approved for serious *S. aureus* infections including bacteremia in adults but is not yet approved for children.[11,83] Tigecycline is another agent most useful for polymicrobial infections including MRSA in adults but has not been studied in children.[268] The role of parenteral trimethoprim-sulfamethoxazole in treating invasive MRSA infections is unclear owing to the paucity of reports.[199] Nafcillin, oxacillin, and cefazolin are the recommended agents for treatment of severe MSSA infections.

For mild to moderate skin and soft tissue infections caused by CA-MRSA, empirical treatment may include other antibiotics such as clindamycin or trimethoprim-sulfamethoxazole. Doxycycline and minocycline are options for children older than 8 years old.[245] If more than 90 percent or so of community *S. aureus* isolates are susceptible to clindamycin, clindamycin can be used for empirical treatment of moderately invasive infections such as in children with osteomyelitis or pneumonia and empyema who do not require intensive care and in whom bacteremia is not thought to be likely. This approach is

not recommended when the clindamycin rate exceeds 10 percent of the CA-MRSA and CA-MSSA isolates combined.[55] Vancomycin or linezolid would be considerations in such circumstances.[145] Once an organism is isolated, therapy is modified based on susceptibility patterns. For moderate MSSA infections, nafcillin, oxacillin, and cefazolin are the preferred parenteral agents and dicloxacillin and cephalexin are the preferred oral agents.

The origin of CA-MRSA is not known. The absence of health care exposure in patients harboring the bacterium, the unique antibiotic susceptibility characteristics of these isolates, and distinctive pulsed-field electrophoresis patterns that are different from the patterns of hospital-acquired MRSA isolates for a given institution suggest that the origin may be the community and that these isolates were not merely transferred from the hospital setting.[3,107] The unique combination of the gene complex and the much smaller SCC*mec* size than identified in the SCC*mec* of hospital-acquired MRSA also suggests a different origin.[184] Whether the origin is the hospital or the community, the changing epidemiology of MRSA is remarkably similar to the emergence of penicillin-resistant *S. aureus* that occurred in the 1940s and 1950s.[40] Finally, the increasing rate of isolation of MRSA will mandate the use of alternative antibiotics, which in turn may promote the development of additional resistance to other antibiotic classes, the one of most concern being resistance to glycopeptide antibiotics such as vancomycin. Although vancomycin is the antibiotic of choice for severe MRSA infection, its use must remain monitored and controlled because clinical isolates with decreased susceptibility to this antibiotic—vancomycin- or glycopeptide-intermediate *S. aureus* (VISA or GISA)—have been reported.[264]

In June 2002, the first documented infection by vancomycin-resistant *S. aureus* in the United States was reported.[38] The isolate, obtained from a catheter exit site of a 40-year-old diabetic patient undergoing chronic dialysis, had high MICs for vancomycin (1024 μg/mL) and oxacillin (>16 μg/mL) but was susceptible to chloramphenicol, linezolid, minocycline, quinupristin-dalfopristin, and trimethoprim-sulfamethoxazole.[38,41] Since then, six additional isolates have been reported from Michigan, Pennsylvania, and New York.[39,279,280] All of the vancomycin-resistant *S. aureus* strains are resistant to the glycopeptides by virtue of the *van*A gene found in the enterococci. VISA strains (MIC of 4 or 8 μg/mL) do not harbor the *van*A gene and are intermediately resistant to vancomycin because of a thickened cell wall containing vancomycin-binding dipeptides.[52,112,121] Vancomycin (and other glycopeptides)-intermediate resistance is not detected by disk diffusion techniques and may not be consistently detected by automated systems.[278] In response to Clinical and Laboratory Standards Institute guidelines, microbiology laboratories have lowered the breakpoints for vancomycin susceptibility to 2 μg/mL or less, for intermediate resistance to 4 to 8 μg/mL, and for resistance to 16 μg/mL or more. In actuality, very few *S. aureus* have MICs greater than 4 μg/mL.[279]

Several studies in adults have reported worse outcomes for vancomycin treatment of MRSA infections, especially bacteremia or ventilator-associated pneumonia, when isolates have a vancomycin MIC greater than 1.0 μg/mL.[113,178,249] The relative increase in vancomycin MIC has been referred to as "vancomycin creep," but the MIC values are dependent on the method used to determine the MIC.[138] MIC results generally are higher using the E-test, but outcome of treatment may correlate better with E-test results compared with other methods.[158] As a result, dosing vancomycin such that the trough concentration remains between 15 and 20 μg/mL to achieve optimal drug exposure is recommended for adults with serious MRSA infection by experts.[175,247] However, "vancomycin creep" does not appear to be a problem in MRSA isolates recovered from children, and higher vancomycin troughs are associated with nephrotoxicity and thus the need to target vancomycin trough levels at 15 to 20 μg/mL is unclear in children.[91,133,179,190,310] Furthermore, doses of vancomycin much higher than the conventional dose (60 mg/kg/day) are often required in children to achieve this trough target. One approach would be to target this trough value for treatment of serious infections when initiating vancomycin but to reduce the dose to 60 mg/kg/day once the patient has clearly improved clinically and blood cultures are negative. Daptomycin and perhaps ceftaroline will likely become the primary options for treating serious invasive infections in children caused by MRSA strains with reduced susceptibility to vancomycin after the optimal doses and safety profiles of these agents have been established in children.

PREVENTION

Staphylococcal infections are so common that virtually everyone has had at least some minor encounters. Skin infections occur more commonly in tropical climates or during warm, humid weather in temperate areas and are likely to arise in moist areas of the body such as the axillae and skin creases. High standards of personal hygiene, careful cleaning, and adequate protection of abrasions and minor lacerations reduce the likelihood of a skin infection developing.[275] Early attention to minor infection in these small wounds with careful cleaning and antibiotic ointment may help prevent more serious or invasive infection. Even minor cutaneous infections can precede the development of more serious staphylococcal infections such as osteomyelitis, pneumonia, and endocarditis.

Person-to-person spread from an overt lesion is a major route for dissemination of infection within families, in hospitals, and in schools. A person with an infected, purulent wound should receive prompt treatment and be excused from school and from such occupations as hospital worker or food handler while the infection is open or draining. At home, special precautions should be taken in care and dressing of the wound. Disposable gauze pads should be used to wash and dry it, and towels and washcloths should not be shared with other members of the family. For children with recurrent infections or for families with multiple family members with infection,

in addition to routine hygienic measures, Fritz and associates[87] found that a 5-day regimen of twice-daily intranasal mupirocin and daily chlorhexidine body washes for everyone in the household reduced the frequency of subsequent skin and soft tissue infections in the child as well as other household members. The Infectious Diseases Society of America guidelines also include mupirocin along with chlorhexidine as part of a strategy to decolonize patients with recurrent skin and soft tissue infections.[175] Resistance to mupirocin or chlorhexidine is likely to increase as these agents are used more frequently in the community for prevention programs.[166,197] Thus, monitoring for resistance to mupirocin and chlorhexidine among *S. aureus* isolates should be more routinely performed. Dilute bleach kills *S. aureus* in vitro very quickly and has been used by dermatologists for years as part of a strategy to prevent staphylococcal skin infections.[76,144] We have found that having the patients take a bath for 15 minutes twice a week in water to which bleach (1 teaspoon/gallon of bath water) has been added decreases the frequency of recurrences, and we are evaluating this approach in a randomized trial.

To date no vaccine targeting polysaccharide or adhesion proteins has been successfully developed for the prevention of *S. aureus* infections.[54,231] One trial using immune globulin enriched for antibody to clumping factor A failed at preventing staphylococcal infections in low-birth-weight infants,[24] and a monoclonal antibody directed against clumping factor A was investigated preliminarily in adults with *S. aureus* bacteremia.[296] A polyclonal IgG preparation containing high levels of antibody to *S. aureus* capsular polysaccharides 5 and 8 has been developed by collecting plasma from healthy donors immunized with StaphVAX.[21] The pharmacokinetics and safety of this product in very-low-birth-weight infants were established in a phase 2 trial, but further development of this antibody preparation is questionable. The safety and pharmacokinetics of human chimeric monoclonal antibody directed against the lipoteichoic acid, an integral component of the cell wall of gram-positive organisms, including *S. aureus*, has been evaluated in a phase 2 study in very-low-birth-weight-infants.[24] This antibody (pagibaximab) also did not appear to be efficacious in preventing invasive *S. aureus* infections in very-low-birth-weight infants.

Perhaps taking advantage of the *S. aureus* genome with a reverse vaccinology approach will lead to a safe and efficacious vaccine.[272] But until such time, simple measures such as frequent hand washing, attention to skin breaks, and avoiding contact of obviously infected skin lesions are the most effective measures to prevent *S. aureus* infections.

CHAPTER 81

Coagulase-Negative Staphylococcal Infections

David Y. Hyun

Coagulase-negative staphylococci are some of the most common pathogens of nosocomial infections. They are also some of the most frequently isolated organisms in the microbiology laboratory, in part owing to their commensal nature with human skin and mucosal membranes. Neonates, immunocompromised patients, and patients with indwelling medical devices are at higher risk for acquiring coagulase-negative staphylococcal infections.[174,191,219,267] Diagnostic challenges remain despite advances in molecular epidemiologic tools, owing to the difficulty of accurately differentiating true infections from contaminated clinical samples. Infections are usually more indolent compared with other gram-positive cocci. Effective therapy can be difficult to achieve because of the high prevalence of resistance to multiple antibiotics. The discussion presented here is focused on the microbiology, epidemiology, pathogenesis, clinical manifestations, diagnoses, and treatment of infections caused by these ubiquitous organisms.

HISTORICAL BACKGROUND

Frederick Julius Rosenbach is credited with identifying *Staphylococcus epidermidis* in 1884, which at the time he named *S. albus* to denote the white colonies and to differentiate it from *S. aureus*, which was observed to have yellow colonies. The *S. albus* term was subsequently used as the descriptive terminology for all coagulase-negative staphylococci until the 1960s. During the 1960s, coagulase-negative staphylococci began gaining recognition as significant infectious pathogens in certain patient populations and were identified as etiologic agents of infections in neonates with sepsis and in adult patients with atrioventricular shunts and peritoneal catheters.[31,33,146,234] As a result, efforts to further differentiate and delineate species of coagulase-negative staphylococci led to the new nomenclature of *S. epidermidis* supplanting *S. albus* as well as to the identification and recognition of *S. saprophyticus* as a pathogen of the urinary tract. Descriptions and identifications of other species followed. Today, there are more than 40 known species of coagulase-negative staphylococci.

MICROBIOLOGY

Staphylococci are gram-positive, nonmotile, non–spore forming, and catalase-positive bacteria. They are members of the family Micrococcaceae along with *Micrococcus*, *Planococcus*, and *Stomatococcus*. Members of the genus *Staphylococcus* have a low DNA G + C content (30 to 39 mol%), whereas members of the genus *Micrococcus* have a G + C content within the range of 66 to 75 mol percent.[134] Staphylococci grow in irregular clusters, which are often described as "grapelike" when viewed microscopically. The cell wall is composed primarily of peptidoglycan with teichoic acid and an assortment of interspersed proteins, many of which are exposed on the surface and interact with host cells.[193] The teichoic acid has a glycerol backbone, in contrast to the ribitol of *S. aureus*.[181] Staphylococci are further divided by their ability to produce coagulase, the enzyme responsible for coagulation of rabbit plasma. *S. aureus* and *S. intermedius* are the two known coagulase-positive species. Most clinical laboratories utilize an alternative agglutination method that targets antigens specific to *S. aureus* to differentiate it from coagulase-negative staphylococci.[111] Fermentation of mannitol is another feature of *S. aureus* that differentiates it from most coagulase-negative staphylococci.

Species identification for coagulase-negative staphylococci requires assessment of a combination of features, including colony morphology, oxygen requirements, novobiocin resistance, aerobic acid production from carbohydrates, and selected liability to enzymatic activities.[132,133] Resistance to novobiocin is observed in *S. saprophyticus*, *S. cohnii*, and *S. saprophyticus*.[200] Commercial kits utilizing rapid biochemical reactions are available to identify species of coagulase-negative staphylococci. Although these kits have varying degrees of confidence and accuracy depending on the species, most systems can reliably identify species most commonly associated with human disease, such as *S. epidermidis*, *S. haemolyticus*, and *S. saprophyticus*.[203] *S. lugdunensis*, which has recently emerged as a significant pathogen in humans, can be differentiated from other coagulase-negative staphylococci by a negative tube coagulase test, a positive pyrrolidonyl arylamidase (PYR) reaction, and positive ornithine decarboxylase activity.[75]

EPIDEMIOLOGY

Coagulase-negative staphylococci are primarily isolated from human skin and mucosal membranes (Table 81-1). The number of commensal coagulase-negative staphylococci on skin can vary from 10 to 10^6 colony-forming units per square centimeter depending on the anatomic

TABLE 81-1 **Coagulase-Negative Staphylococci Commensal to Human Skin and Mucosal Membranes**

Species	Anatomic Site	Pathogenic Potential
S. epidermidis	Nares, axillae, skin	Common
S. saprophyticus	Occasionally skin	Common
S. haemolyticus	Skin of head, arms, and legs	Uncommon
S. hominis	Axillae, skin of head, arms, and legs	Uncommon
S. lugdunensis	Widely distributed on body	Uncommon
S. simulans	Occasionally skin	Uncommon
S. cohnii	Occasionally skin	Uncommon
S. warneri	Occasionally skin	Uncommon
S. saccharolyticus	Rarely skin	Rare
S. caprae	Occasionally skin	Rare
S. capitis	Skin of head, face, ears, and arms	Rare
S. auricularis	Ears	Rare
S. schleiferi	Skin	Rare
S. xylosus	Occasionally skin	Rare

location, with some species demonstrating a predilection for colonizing specific body sites.[135] Colonization can begin as early as the neonatal period. Two studies addressed the colonization of *S. epidermidis* in low-birth-weight neonates,[50,98] with both reports describing rapid colonization, in which 75 percent of neonates were colonized by 2 weeks of age. Although most infants acquire coagulase-negative staphylococci from environmental sources, including hospital personnel, a few are colonized by vertical transmission.[23,97,194]

Eighteen species have been isolated from humans. *Staphylococcus epidermidis* continues to be the predominant species identified among commensal and clinical isolates.[275] Most coagulase-negative staphylococci cause nosocomial infections frequently associated with indwelling prosthetic devices such as central venous catheters. As a result, the increase in use of these medical devices has led to a proportional increase in the rates of infections.[219] *S. saprophyticus* and *S. lugdunensis* are notable exceptions that have been associated with community-acquired urinary tract infections and native-valve endocarditis, respectively.[12,144]

Epidemiologic typing methods are used in coagulase-negative staphylococcal infections when investigating a common-source outbreak or repeated infections within an individual (Table 81-2).[180,203,267] Older phenotypic typing tools such as antibiotic susceptibility pattern analysis, biochemical reactivity, slime production detection, and serologic typing lacked the power to differentiate closely related strains and were hampered by poor sensitivities and specificities.[246,275] In contrast, molecular genotyping methods have demonstrated higher discriminatory power with pulse-field gel electrophoresis (PFGE) becoming the method of choice when investigating patterns of transmission and sources of outbreaks.[27,143,169,254,267] Random amplification of polymorphic DNA (RAPD) by polymerase chain reaction (PCR) also has been successful in identifying clonal outbreaks and transmissions. Although it is less discriminatory than is PFGE, RAPD is less costly and time consuming.[24,210] Multilocus sequence typing (MLST) can be used to delineate clonal relationships between strains and has been used to identify predominant clones from a group of clinical isolates.[154,283]

PATHOGENESIS

Risk factors for coagulase-negative staphylococcal infection are associated with nosocomial interventions that modify or bypass the host defense and immune mechanisms. They include immunosuppression,[71,126] prior antibiotic therapies,[127,235] and breakdown of mucocutaneous barriers, which is most commonly seen with the presence of prosthetic devices such as central venous catheters, cerebrospinal fluid (CSF) shunts, and peritoneal dialysis catheters.[13,20,66,149]

Biofilms (Fig. 81-1) are major virulence factors for coagulase-negative staphylococci especially in infections associated with prosthetic devices.* They are agglomerates of bacteria embedded in extracellular material and provide a mechanism of evasion against host defense and antibiotic activities.† They act as mechanical barriers to most immune cells, interfere with phagocytic activity, and limit antibiotic diffusion. Biofilm formation occurs in steps, with initial attachment followed by accumulation and detachment.

The initial attachment of *S. epidermidis* to polystyrene and other surfaces[154,155] is primarily mediated by several microbial surface components recognizing adhesive matrix molecules (MSCRAMMs).[107,112,220,256,270] MSCRAMMs facilitate binding to specific human matrix proteins,

including fibrinogen, fibronectin, vitronectin, and collagen. Nonspecific electrostatic and hydrophobic interactions[104,109,258] and teichoic acids[112] also play roles in adhesion. Initial adhesion is followed by intercellular aggregation and accumulation of biofilms mediated by production of polysaccharide intercellular adhesion (PIA),[106,221] which acts as the primary component for the extracellular matrix of *S. epidermidis*. In addition to its role in biofilm formation, PIA also acts as a hemaglutinin[154,218] and provides protection against phagocytosis and killing by human polymorphonuclear leukocytes.[239,271] The *ica* operon encodes enzymes necessary for PIA production.[106]

In numerous epidemiologic studies, the presence of the *ica* operon has been associated more frequently with *S. epidermidis* strains isolated from hospitalized patients with prosthetic device infections than with community strains isolated from healthy individuals. Eighty-one to 89 percent of isolates from hospitalized patients have been reported to carry the *ica* operon. In contrast, only 6 to 38 percent of community-acquired isolates were found to carry the *ica* operon.[76,137,259] However, utilizing *ica* operon detection to differentiate between invasive and commensal strains of *S. epidermidis* has proven to be unreliable. Investigations of clinical strains obtained from patients in neonatal intensive care units, bone marrow transplant units, and oncology units have shown that although both invasive and commensal strains demonstrated high carriage rates of the *ica* operon, no significant difference was found between the two groups.[28,56,197,214] Higher proportions of invasive strains demonstrated biofilm production in quantitative assays compared with commensal strains.[28,214] Most of the commensal strains were biofilm-negative despite possessing the *ica* operon, a finding suggesting that regulation of gene expression plays a large role in virulence. Clinical strains of *S. epidermidis* producing biofilms independently of PIA have also been described.[136,213,214]

Unlike *S. aureus*, which is capable of producing various cytolytic and superantigenic toxins, *S. epidermidis* produces very few toxins.[269] More recently, phenol-soluble modulins (PSMs) have been identified and characterized as a family of peptides produced by *S. epidermidis* with cytolytic and proinflammatory capacities.[41,165] *Delta* toxin is part of the PSM complex and is an enteropathogenic toxin encoded by the *hld* component of the regulatory system agr that has been linked to necrotizing enterocolitis in infants.[232] *S. epidermidis* also produces antibacterial peptides called *lantibiotics* that may play a role in bacterial interference on skin and mucous membranes and in the creation of an ecologic niche for *S. epidermidis*.[141] Numerous extracellular enzymes are also produced by coagulase-negative staphylococci; an extracellular metalloprotease with elastase activity; a cysteine protease that degrades human secretory immunoglobulin A, immunoglobulin M, serum albumin, fibrinogen, and fibronectin; and an extracellular serine protease involved in epidermin processing.[105,269,273] Two lipases have been postulated to facilitate skin colonization.[105,269]

S. saprophyticus can cause urinary tract infections in the absence of indwelling catheters.[141] Several virulence factors have been described to explain its pathogenic potential to adhere and persistently grow in the urinary tract. A surface-exposed protein with hemagglutinin and adhesive properties[83] and a surface fibrillar protein,[82] designated *ssp*, are associated with attachment to urinary tract epithelium. Urease production also has been associated with invasiveness of this organism by causing damage to bladder tissues.[80,81] The whole genome of *S. saprophyticus* has been sequenced and compared with *S. aureus* and *S. epidermidis*.[141] Analysis revealed a single, unique cell wall–anchored protein with properties of hemagglutination and adherence to human bladder cells. A high population of ionic transport systems capable of providing osmotolerance in the highly variant ionic environment of urine also was demonstrated.

CLINICAL MANIFESTATIONS

Coagulase-negative staphylococci have been implicated in a variety of clinical infections, which are mostly nosocomial in immunocompetent and immunocompromised patients (Table 81-3).[133,191,222] Because of the commensal nature of these organisms, separating true infections from contaminated culture results continues to be a challenge. This is further compounded by the variability among clinical studies when defining the criteria for clinically significant cultures.[61] Repeated isolation of the same phenotypic or genotypic strains of coagulase-negative staphylococci can facilitate interpretation. Quantitative cultures can also add value in the diagnosis of catheter-associated bacteremia by demonstrating a five- to tenfold increase in the number of colony-forming units in cultures obtained from a catheter compared with cultures from a peripheral vessel. The Committee on Infectious Diseases of the American Academy of Pediatrics suggested the following considerations to distinguish pathogenic from contaminant coagulase-negative staphylococci: (1) two or more positive blood cultures from

different sites, (2) a positive culture from blood and another usually sterile site with identical or nearly identical antimicrobial susceptibility patterns, (3) growth in continuously monitored blood culture system within 15 hours of incubation, (4) clinical findings of infection, (5) an intravascular catheter that has been in place for 3 days or more, and (6) similar or identical genotypes among all isolates.[4]

Clinical presentation markedly differs from that of *S. aureus* infection. In general, infections caused by coagulase-negative staphylococci are more indolent and can have a subacute or even chronic course. They occur mostly as health care–associated bacteremia and infections of prosthetic medical devices.

Bacteremia

Coagulase-negative staphylococci, particularly *S. epidermidis*, are the most common pathogens in nosocomial bloodstream infections and have become the major nosocomial pathogens in most studies.[61,212] An analysis of 6,290 nosocomial infections in 110,709 patients from 61 pediatric intensive care units in the United States during 1992 to 1997 showed that coagulase-negative staphylococci were the causative agents in 38 percent (717 of 1887) of nosocomial bloodstream infections.[212] In another large surveillance study between 1995 and 2001 among 49 hospitals in the United States, coagulase-negative staphylococci were identified in 43 percent of nosocomial bacteremias in pediatric patients.[277] Among oncologic immunocompromised pediatric patients, coagulase-negative staphylococci accounted for up to 35 percent of all positive blood culture isolates.[2,11,142] A significant majority of all coagulase-negative bacteremia occurs with the use of indwelling vascular catheters.

Neonatal Bacteremia

Coagulase-negative staphylococci are the most frequent cause of late-onset septicemia and bloodstream infections among premature infants.* These infections are found predominantly in premature infants with a gestational age of less than 34 weeks and those with low birthweights,[88,102,116,192] owing to their higher likelihood of prolonged use of a central catheter and parenteral nutrition and their immature immune system, including quantitative and qualitative neutrophil deficiencies.[36,242,277] The presence of indwelling peripheral or umbilical catheters has been implicated in approximately half of neonatal coagulase-negative staphylococcal bacteremias.[17,96,178,187] The salient features from six large studies are listed in Table 81-4.†

Clinical findings of coagulase-negative staphylococcal bacteremia are mostly indolent and subtle and include bradycardia, apnea, and temperature instability (see Table 81-4). The frequency of fulminant late-onset sepsis caused by coagulase-negative staphylococcal bacteremia is very low (1%).[125] Mortality rates associated with coagulase-negative staphylococcal infections in neonates are much lower compared with those with other pathogens.[156,249] However, neonates with prolonged and persistent bacteremia have higher mortality rates that are comparable to those of other pathogens.[39,116]

Laboratory studies need to be interpreted within clinical contexts and risk factors consistent with coagulase-negative staphylococcal bacteremia.[102,110,161,175] Leukocytosis may not be present, and there have been conflicting findings in regard to the utility of biofilm detection as a marker for infection.[96,192] Use of quantitative blood cultures correlated with clinical criteria may have a role in identifying the true pathogen.[248] The U.S. Centers for Disease Control and Prevention (CDC) defines laboratory-confirmed bloodstream infections for common skin contaminants including coagulase-negative staphylococci in patients 1 year or younger as (1) at least one finding of fever, hypotension, or chills; (2) signs, symptoms, and laboratory findings not consistent with infection at another site; and (3) isolation of an organism from two or more blood cultures drawn on separate occasions.[110]

Persistence of coagulase-negative staphylococcal bacteremia despite administration of adequate antibiotic therapy has been described in neonates.[60,130,192] Mean duration of persistent bacteremia is 10 to 14 days. This persistence was observed in patients with and without central venous catheters and in patients with normal findings on cardiac echocardiography. Neonates with

persistent bacteremia had a significantly higher incidence of severe thrombocytopenia requiring platelet transfusions than did those with nonpersistent bacteremia.[60,130]

Rarely, coagulase-negative staphylococcal meningitis in the absence of intraventricular devices has been reported in low-birth-weight neonates with normal CSF white blood cell counts.[93] CSF examination may be considered in neonates with coagulase-negative staphylococcal bacteremia because abnormal CSF findings or a positive CSF culture may influence the duration of therapy. Coagulase-negative staphylococci also have been implicated as etiologic agents of necrotizing enterocolitis,[92,232] although one report showed no association.[217]

Bacteremia in Immunocompromised Patients

Immunocompromised patients with leukemia or lymphoma are at risk for coagulase-negative staphylococcal bacteremia (Table 81-5).* In several reports, coagulase-negative staphylococci were the isolates most commonly

*References 2, 11, 78, 142, 204, 205, 236.

causing bacteremia in pediatric patients with cancer and accounted for 35 to 50 percent of all initial isolates.[2,11,142,195] One third of these patients did not have central venous catheters at the time of their bacteremia.[78] Risk factors for this patient population include indwelling catheters, malnutrition, and myelosuppression, especially neutropenia after chemotherapy. In addition to catheter-associated bacteremias, translocation of pathogens through inflamed mucosal surfaces secondary to chemotherapy, including the gastrointestinal tract, is a prominent mechanism of bacteremia. One study utilizing molecular epidemiologic tools, including RAPD and PFGE analysis of clinical isolates obtained from adult neutropenic oncology patients, showed that skin flora was the likely source for 75 percent of coagulase-negative staphylococcal catheter-associated infections.[180]

Coagulase-negative staphylococci have also become the primary pathogens for bacteremia among hematopoietic stem cell transplant recipients.[32,167] These episodes occur most often during periods of agranulocytosis before marrow engraftment,[32] and they can be fatal.[19] Most bacteremic episodes are due to use of central venous catheters and broad-spectrum antibiotics.

Significant morbidity from coagulase-negative staphylococcal bacteremia can be attributed to the organism's acquisition of multiple antibiotic resistance that requires the use of antimicrobial agents with a higher risk for toxicity, such as vancomycin or linezolid.* Mortality rates have varied from 0 to 11 percent.[78,142]

Indwelling Medical Devices

Intravascular Catheter-Related Infections

Coagulase-negative staphylococci are the most common pathogens for catheter-related infections.[74,166,278] Risk for infections varies among the different types of catheters. Short-term central venous catheters (CVCs), defined as those in place for fewer than 14 days, account for the majority of catheter-related infections. Peripherally inserted central catheters (PICCs) carry similar risks of infection to those of short-term CVCs when used in intensive care units.[166] However, the frequency of catheter-related infections for PICCs used for outpatient parenteral therapies appears to be significantly lower.[148,263] Long-term CVCs that are surgically implanted with a tunneled portion and a Dacron cuff just inside the skin exit site[30,108] also have lower infection rates at 0.14 per 100 catheter-days,[111] with the catheter hub being the major source of infection.[208] Finally, totally implanted vascular devices with subcutaneous ports or reservoirs carry the lowest infection risk, with rates of 0 to 0.04 per 100 catheter-days.[111,216] Infections at the catheter insertion sites also can lead to bacteremia or septic thrombophlebitis, with further complications caused by metastatic spread.[207] Overall, infectious complications involving central venous catheters have a variable reported frequency of 2.7 to 47 percent,† with coagulase-negative staphylococci identified as the pathogens in approximately half of these cases. The wide range of frequency is attributed to the intended use of the catheters, types of catheters, frequency of catheter access, characteristics of patients, and use of preventive strategies.[166]

As with other coagulase-negative staphylococcal infections, *S. epidermidis* is the predominant species associated with catheter-related infections, accounting for approximately 70 percent of cases.[20,101] This likely correlates to the high prevalence of the organisms colonizing the human skin.[135] Other implicated coagulase-negative staphylococcal species include *S. haemolyticus*, *S. warneri*, and *S. hominis*.[101]

Establishing accurate diagnoses of catheter-related coagulase-negative staphylococcal infections remains a challenge owing to the difficulty of differentiating true infections from contaminated specimens and depends on the patient's clinical status and the isolation of identical strains from repeated cultures. In addition, it is important to distinguish catheter-related bacteremia from bacteremia caused by infections at other sites. The use of quantitative blood cultures has shown that catheter-related bacteremia has a 5- to 10-fold difference in bacterial concentration in blood cultures drawn from the catheter when compared with the concentration in peripheral cultures.[73,211] When a catheter is removed because of a suggested catheter-related infection, a semiquantitative culture of the distal 5 cm of the catheter is recommended.[166] This can be accomplished by rolling the distal portion of the catheter on a culture plate. Growth of more than 15 colony-forming units is indicative of catheter colonization.[157]

Duration of antimicrobial therapy for uncomplicated coagulase-negative staphylococcal catheter-related infections depends on whether the catheter is removed or retained.[166] When the catheter is no longer needed, it should be removed and the patient should be given 5 to 7 days of antimicrobial therapy. If the catheter is retained, the duration of antimicrobial therapy should be 10 to 14 days and accompanied by antibiotic lock therapy. Therapy with retention of a catheter carries a higher risk for recurrence.[209] Complicated catheter-related infections, including those with tunnel infections, port abscesses, septic thrombosis, endocarditis, and osteomyelitis, are indications for catheter removal. *S. lugdunensis* infections should be treated more conservatively in a manner similar to *S. aureus* infections owing to the higher virulence of this organism compared with other coagulase-negative staphylococci.

Central Nervous System Shunts

Coagulase-negative staphylococci are the predominant pathogens for infections of central nervous system shunts that are used to relieve hydrocephalus by diverting CSF infections.[129] They account for 60 to 75 percent of all bacterial causes of shunt infections.[129,176,240] Ventriculoperitoneal shunts that divert CSF into the peritoneal cavity have primarily been used since the 1960s because of their lower rate of mechanical complications.[129,173,182] Ventriculoatrial shunts that divert CSF into the right atrium are used infrequently because of higher

*References 78, 126, 142, 152, 153, 206, 229.
†References 20, 85, 101, 151, 170, 244, 268.

complication rates.[182] However, the incidences of infection involving both ventriculoperitoneal and the ventriculoatrial shunts are comparable.[129,182,240] Infection rates are higher in neonates.

Shunt infections can begin at the insertion site by contamination of the catheter from the patient's skin flora[240] or during subsequent revisions. Short-term infection rates are reported to be 13 percent, and 10-year infection rates are 27 percent.[215] Seventy percent of ventriculoperitoneal shunt infections occur within the first 2 months after placement.[176]

CSF examination can be helpful in patients with signs and symptoms consistent with a shunt infection. Gram stain of ventricular fluid is often negative, but culture is sensitive. Subtle changes are noted in CSF and ventricular fluid cell counts or cytochemical findings.[280] Patients with ventriculoatrial shunts often have signs and symptoms compatible with septicemia. In patients with ventriculoperitoneal shunts, an intra-abdominal cyst may develop at the distal end of the catheter. Dysfunctions of the shunt secondary to development of infections often lead to signs and symptoms consistent with increased intracranial pressure. Standard therapy for ventriculoperitoneal shunt infections has been removal of the shunt system and administration of systemic antibiotics.[240,280,282]

Peritoneal Dialysis Catheters

S. epidermidis is the bacterial pathogen most commonly isolated in peritoneal dialysis catheter infections,[91,201] accounting for up to 50 percent of infections.[201] These include catheter exit site infections as well as peritonitis.[201] The prevalence of peritonitis in patients undergoing continuous ambulatory peritoneal dialysis is approximately 60 percent. Signs of peritonitis include fever, abdominal pain, and cloudy peritoneal dialysis fluid. Removal of the catheter usually is not necessary for successful therapy but may be required in refractory cases or when the catheter malfunctions. Antibiotics can be administered systemically as well as intraperitoneally through the dialysis fluid.[69]

Prosthetic Valves

Coagulase-negative staphylococci are frequent pathogens causing prosthetic valve endocarditis, accounting for approximately 17 percent of contemporary cases.[52,274] This is in contrast to native valve endocarditis for which coagulase-negative staphylococci are rarely isolated. Although many cases of coagulase-negative staphylococcal prosthetic valve endocarditis occur within 60 days of device implantation,[147] they can also occur as late as 1 year after surgery, with inoculation of the organism at the time of surgery followed by abscess formation of the valvular ring being the likely mechanism.[27] Signs and symptoms can vary, but fever is the most common finding. Typical findings of endocarditis caused by other pathogens such as peripheral emboli can be mostly absent in coagulase-negative staphylococcal endocarditis, owing to the organism's indolent nature. Anemia is the abnormality identified most often by laboratory testing. Evaluation should include multiple blood cultures and echocardiography. The antimicrobial regimen for prosthetic valve endocarditis caused by coagulase-negative staphylococci usually involves vancomycin and rifampin for a minimum of 6 weeks along with gentamicin for the first 2 weeks because the majority of organisms are methicillin resistant.[14] Surgery may be indicated when infection is complicated by perivalvular or myocardial abscesses.

Other Indwelling Medical Devices

Coagulase-negative staphylococci are involved in an expanded spectrum of infections involving indwelling medical devices.[57,89] They include infections of prosthetic joints,[70,124] vascular grafts,[15,62] hemodialysis shunts,[189,233,234] and pacemaker pockets.[42,115,158,199] Additionally, osteomyelitis secondary to *S. epidermidis* has been reported to occur after hemodialysis and in neonates after the use of a monitoring scalp electrode.[183]

Native Valve Endocarditis

Native valve endocarditis along with *S. saprophyticus* urinary tract infection are the only non-nosocomial infections caused by coagulase-negative staphylococci.[118] Approximately 7 percent of cases of native valve endocarditis are caused by coagulase-negative staphylococci, and *S. epidermidis* is the most frequently isolated species.[46] These infections usually are subacute and arise from transient bacteremia. Pathogenesis is thought to involve seeding of a previously damaged valve or endocarditis that had not been previously identified.[6,18]

S. lugdunensis can cause acute, severe, and destructive endocarditis similar to *S. aureus* endocarditis,[261] with most favorable outcomes occurring in patients who undergo valve replacement.[53] Most patients with *S. lugdunensis* endocarditis have been older than 50 years of age. Mortality rates are higher compared with infections by other species.[12] Native aortic or mitral valves are involved most frequently.[260] The perineum appears to have a high colonization rate of *S. lugdunensis.*[120]

Surgical Site Infections

Coagulase-negative staphylococci are the second most common cause of postoperative surgical site infections, according to National Nosocomial Infections Surveillance Report survey data.[38] Most infections are likely caused by the patient's own endogenous skin flora, but outbreaks originating from operating room personnel have been reported.[27] Outbreaks of *S. epidermidis* surgical site infections, such as mediastinitis and endocarditis, among patients who have undergone cardiac valve replacements also have been reported.[26,210]

Urinary Tract Infections

S. saprophyticus is the most common coagulase-negative staphylococcal species that causes infections in both the upper and the lower urinary tracts.[144] These infections occur predominantly in young, healthy, sexually active women,[121,144,161] during late summer and fall, with a

pattern similar to that of sexually transmitted diseases.[80] Recent sexual intercourse, outdoor swimming, and occupational meat processing have been identified as risk factors.[80] *S. epidermidis* and other coagulase-negative staphylococci rarely cause urinary tract infections, but they have been noted to produce disease in older adults with urinary tract complications.[94,150,177] McDonald and Lohr[163] and Hall and Snitzer[95] described healthy children with pyelonephritis caused by *S. epidermidis*.

Miscellaneous Infections

Endophthalmitis secondary to *S. epidermidis* has been reported in patients undergoing ocular surgery or trauma.[16,29,202] One center reported coagulase-negative staphylococci as being the most common organisms isolated from patients with culture-positive endophthalmitis over a 20-year period, accounting for 38 percent of the cases.[40] Postoperative mediastinitis that develops after median sternotomy for open heart surgery can be caused by *S. epidermidis*.[25,65,90] Primary osteomyelitis secondary to coagulase-negative staphylococci is a rare occurrence in healthy children.[184] *S. caprae*[241] and *S. lugdunensis*[227] have been linked to bone and joint infections. Coagulase-negative staphylococci also have been implicated as a possible cause of toxic shock syndrome.[49]

TREATMENT

Vancomycin is the drug of choice for most coagulase-negative staphylococcal infections, owing to the high prevalence of methicillin resistance especially among nosocomial strains.[3,224,243] When susceptibility data are not available, vancomycin should be used for empirical therapy. If the coagulase-negative staphylococcus is known to be susceptible to methicillin, oxacillin or nafcillin is the preferred therapeutic agent.[203,225]

Most coagulase-negative staphylococci, particularly *S. epidermidis* and *S. haemolyticus*, are resistant to multiple antibiotics, including methicillin.* Cross-resistance exists between penicillinase-resistant penicillins and cephalosporins. Therefore, methicillin-resistant coagulase-negative staphylococci should be considered as cephalosporin resistant even if routine susceptibility testing indicates susceptibility to cephalosporins.[91,117,145,224] Methicillin-resistant coagulase-negative staphylococci are often resistant to other antibiotics, such as clindamycin, erythromycin, and gentamicin.[7] The *mecA* gene is responsible for methicillin-resistance because it encodes a penicillin-binding protein (PBP2a) that interferes with the binding of β-lactams to the bacterial cell wall.[105,113] The same mechanism accounts for methicillin resistance in *S. aureus*. Despite the understanding of the mechanism, consistent detection of methicillin resistance for coagulase-negative staphylococci can be a challenging process in the clinical laboratory owing to heterogeneous expression of the *mecA* phenotype in minimal inhibitory concentration or disk diffusion testing with only a minority of the bacterial population expressing the resistant phenotype.[7,113,224,279] To facilitate more reliable detection, the Clinical and Laboratory Standards Institute revised specific breakpoints for coagulase-negative staphylococci in 2007 (Table 81-6).[47] In addition, to enhance phenotypic expression of methicillin resistance, the use of lower incubation temperatures of 30° to 35° C for prolonged periods and of increased sodium chloride content in culture medium is recommended.[159,164,223] Molecular detection of the *mecA* gene is an accurate method to predict methicillin resistance.[113]

TABLE 81-6 **Breakpoints for Antibiotic Susceptibility for Coagulase-Negative Staphylococci**

	Oxacillin-Susceptible	Oxacillin-Intermediate	Oxacillin-Resistant
MIC			
CoNS	≤0.25 μg/mL		≥0.5 μg/mL
S. aureus	≤2 μg/mL		≥4 μg/mL
Zone Size			
CoNS	≥18 mm	No intermediate zone	≤17 mm
S. aureus	≥13 mm	11-12 mm	≤10 mm

CoNS, coagulase-negative staphylococci; MIC, minimal inhibitory concentration.
Data from Clinical and Laboratory Standards Institute. Performance testing for antimicrobial susceptibility testing, 17th informational supplement M100-S17, 2007.

Coagulase-negative staphylococci were the first organisms in which glycopeptide resistance was recognized in 1986.[235] A prolonged course of vancomycin is a well-recognized risk factor for the emergence of strains with decreased susceptibility to glycopeptides.[22,279] Although they are uncommon occurrences, infections caused by these strains have been described and may become more common. To prevent or delay development of resistance, the CDC published recommendations for the prudent use of vancomycin.[37] Decreased susceptibility occurs more frequently to teicoplanin than to vancomycin.[9,140,276] The minimal inhibitory concentrations of teicoplanin usually fall over a wide range, whereas vancomycin minimal inhibitory concentrations tend to remain more stable over a narrower range within the limits of susceptibility.[22] Intermediate resistance to vancomycin in coagulase-negative staphylococci has been rarely described.[228,235,264] Thickened cell walls, as seen by electron microscopy and altered cell metabolism that affects vancomycin binding, may be associated with glycopeptide resistance mechanisms.[105]

Gentamicin and rifampin are active against coagulase-negative staphylococci, but rapid emergence of resistance has limited their use as single-drug regimens.[43,162,225] However, these two antibiotics have been shown to be synergistic with vancomycin against methicillin-resistant, coagulase-negative staphylococci.[152] Additionally, rifampin

*References 7, 9, 43, 54, 68, 86, 235, 247, 276.

has been used in neonates with persistent bacteremia to eradicate the organisms.[251,262] Combination therapies utilizing gentamicin or rifampin are frequently used for prosthetic device infections including endocarditis and CSF shunt infections.

Quinupristin-dalfopristin,[10] linezolid,[222] daptomycin,[138,226] and tigecycline[79,138] have all demonstrated significant in vitro activities against coagulase-negative staphylococci and may have a role in the treatment of multidrug-resistant strains. However, there is a paucity of clinical efficacy data, especially compared with the number of studies available for the treatment of methicillin-resistant *S. aureus*. Linezolid resistance in coagulase-negative staphylococci has been described and linked to increased utilization.[128,171]

PREVENTION

Preventing the development of coagulase-negative staphylococcal infection is difficult because of the ubiquitous and commensal nature of these organisms. A 3-year molecular analysis of coagulase-negative staphylococcal nosocomial infections in a neonatal intensive care unit showed that many of the infections were caused by clonal dissemination and potentially were preventable by hand washing, thus reducing the transmission rate from staff to patient or from patient to patient.[267]

Developing catheters that are both inert and resistant to bacterial colonization adherence has been only marginally successful.[131,190,198] The technique of impregnating the surface of catheters with antibiotics or disinfectants appears promising.[253] Prophylactic antibiotics are administered routinely for surgical procedures involving placement of a prosthetic device or material. However, the antimicrobial of choice to prevent infections caused by coagulase-negative staphylococci varies among institutions.[3] Vancomycin often is recommended for placement of a CSF shunt or prosthetic valve.

Infection control policies such as standardizing or "bundling" procedures for aseptic intravascular catheter placement and care is the single most important factor in preventing catheter-associated infections. Standard precautions should be used for methicillin-resistant, coagulase-negative staphylococci. For vancomycin-intermediate, coagulase-negative staphylococci, contact transmission precautions for multidrug-resistant organisms should be used.[4]

CONCLUSION

Coagulase-negative staphylococci, particularly *S. epidermidis*, are a major source of nosocomial infection in a variety of clinical situations. Most infections occur in patients who have indwelling medical devices. Epidemiologic studies have been limited by the commensal nature of the organisms, but newer molecular tools may help investigators to gain further insight and to differentiate true infections from contaminants. Therapy can be complex because of the usual presence of an indwelling medical device and the multiple antimicrobial resistances of the organisms.

CHAPTER 82

Group A, Group C, Group G Beta Hemolytic Streptococcal Infections

Linette Sande • Anthony R. Flores

Streptococcus pyogenes is the only organism within the group A β-hemolytic streptococci (GAS). GAS are among the most common pathogens that infect children and adolescents and are capable of causing a wide range of infections, including relatively benign pharyngitis and life-threatening invasive infections. Despite their uniform susceptibility to penicillin, GAS remain significant clinical and public health problems in this age group. Worldwide, it is estimated that GAS are responsible for more than 500,000 deaths, the majority of which occur in underdeveloped countries.[27] GAS is unique among pyogenic streptococci in its ability to produce postinfectious sequelae such as acute rheumatic fever and acute poststreptococcal glomerular nephritis (APSGN). Infections caused by GAS were brought to the forefront in the United States in the late 1990s with a resurgence of acute rheumatic fever[97,152] and the appearance of serotype M1 and M3 strains causing severe morbidity and mortality.[9,150]

ORGANISM

GAS are gram-positive cocci, generally less than 2 μm, and tend to grow in chains in liquid media. GAS produce clear zones of hemolysis (β) on blood agar, differentiating them from streptococci producing partial (α) and nonhemolytic (γ) streptococci. Hemolysis is best observed when GAS are grown on agar containing 5 percent sheep blood. Some strains of GAS may appear to produce only partial hemolysis on blood agar plates. However, clear hemolysis can more easily be observed when grown anaerobically or by making a short cut or stab into the agar at the time of inoculation.[76] GAS are rarely nonhemolytic.[72,74] They can be differentiated from other β-hemolytic streptococci by their group-specific polysaccharide in the cell wall, the basis for latex agglutination and enzyme immunoassays, or by inhibition of growth by bacitracin.

GAS are frequently categorized or typed based on serologically distinct surface proteins, the M proteins, or by sequencing the gene encoding the M protein, *emm*.[43,44,76,86] The M protein is a major virulence factor of GAS. Acquired immunity to GAS is based, at least in part, on specific opsonic antibodies targeted against the M protein.[85] N-terminal sequence variation in the gene encoding the M protein has led to the description of approximately 200 different *emm*-types,[13] and many more are being added to a curated database publicly available through the Centers for Disease Control and Prevention (CDC).[31] Certain GAS M serotypes have been associated with specific diseases and can be classified as skin or pharyngitis "specialists"; however, some M serotypes have the capacity to cause both types of infection.[15]

The GAS cell is complex and contains many antigenic substances. Freshly isolated clinical strains are typically covered with a hyaluronic acid capsule that is structurally similar to that found in mammals, including humans, and thus is nonimmunogenic.[19,49,80] The GAS capsule gives colonies a mucoid appearance. The M protein is a major constituent of the cell surface, and proteins similar to M protein have been identified. Genes encoding M and M-like proteins (e.g., *enn* and *mrp*) are part of an *emm* gene superfamily. Also found on the cell surface, protruding through the hyaluronic acid capsule, are fimbriae composed of lipoteichoic acid[12] that are frequently associated with M protein.[48] The surface proteins T and R and serum opacity factor are proteins of interest in part because of classification schemes based on each. The T protein is part of the GAS pilus structure,[98] and T-agglutination patterns are generally associated with specific M serotypes.[73] In strains that produce serum opacity factor, the serologically specific serum opacity factor proteins are closely correlated with a particular M serotype.[14]

The GAS cell surface contains a polysaccharide polymer of rhamnose with side-chains of N-acetyl-glucosamine. The carbohydrate is found in sufficient quantities for antibody detection and forms the basis for group specificity originally described by Lancefield.[85] Rigidity of the cell is provided by peptidoglycan consisting of alternating residues of N-acetyl-muramic acid and N-acetyl-glucosamine linked by a peptide bond. Lysozyme produced on mucosal surfaces and by phagocytic cells hydrolyzes the carbohydrate backbone, leading to lysis of the cell and release of bacterial fragments. Detection of the bacterial fragments by host pattern recognition receptors leads to initiation of the host immune response to infection. Some streptococci are able to modify their peptidoglycan, leading to lysozyme resistance,[39] and alter the host immune response. Whether GAS has this capability is unknown.

The innermost layer of the cell wall consists of the cell membrane composed of lipoprotein or lipid–protein complexes. Wall-less forms of streptococci, termed *L forms*, are osmotically fragile and lack the outermost constituents of the GAS cell wall. GAS L forms are of interest because of their resistance to penicillin[52] and their potential role in persistence.[96,97]

In addition to cell surface components, GAS produces many extracellular products. Among these are two distinct hemolysins: streptolysin O and streptolysin S. Streptolysin O, designated so because of its oxygen lability, is toxic to erythrocytes and many other cell types, including phagocytes. Streptolysin O is produced by almost all GAS strains, is antigenic, and measurement of anti–streptolysin O (ASO) antibodies is used as an indicator of GAS infection. Streptolysin S is stable in the presence of oxygen, heat labile, and not antigenic. Hemolysis on the surface of blood agar is the result of streptolysin S; streptolysin O results in hemolysis in the subsurface or in anaerobic conditions.

Several extracellular proteins allow the spread of GAS through tissue. Deoxyribonucleases (DNAses A, B, C, and D) break down extracellular DNA and are believed to facilitate escape from neutrophil extracellular traps consisting in large part of DNA.[24] Spread through connective tissue is achieved through the action of hyaluronidases that enzymatically degrade hyaluronic acid, a major component of connective tissue. GAS streptokinase dissolves clots through conversion of plasminogen to plasmin. GAS produces a C5a peptidase that specifically cleaves C5a, inhibiting phagocyte recruitment. Originally thought to be a GAS superantigen, streptococcal pyrogenic exotoxin B (SpeB) is a potent protease critical in the pathogenesis of severe invasive disease.[28]

The streptococcal pyrogenic exotoxins (Spe) constitute a family of bacterial superantigens believed to be associated with streptococcal toxic shock syndrome and the pathogenesis of severe infections. SpeA and SpeC are bacteriophage-encoded and are associated with scarlet fever (i.e., scarlatinal toxins). Outbreaks of streptococcal toxic shock syndrome in the United States have been associated with strains producing SpeA.[34] Development of streptococcal toxic shock syndrome is multifactorial, and susceptibility may be associated with specific human leukocyte antigen haplotypes.[82]

TRANSMISSION AND EPIDEMIOLOGY

GAS are found almost exclusively in humans and rarely occur in other species.[86] Distinct and significant differences exist in the epidemiology and transmission of GAS based on the site of infection.[118,156]

Streptococcal pharyngitis is one of the most common infections of childhood. Whereas GAS cause the majority of infections, strains of other serogroups, including groups C and G, may instead be involved. GAS pharyngitis occurs primarily in children aged 5 to 15 years, with the peak incidence occurring during the first school years. Severe epidemics may occur in conditions of overcrowding, including daycare centers,[1] residential facilities,[117] and military barracks.[155] The effect of crowding may explain, at least in part, the seasonal occurrence in temperate and cold climates. Contaminated foods (e.g., milk and egg salad) may result in outbreaks of GAS pharyngitis.[69,91] Fomite contamination and airborne routes are unlikely to play any role in the spread of GAS pharyngitis.[30]

The mechanism of spread is facilitated by close personal contact. Early studies demonstrated that large droplets or direct transfer of respiratory secretions containing large amounts of infectious bacteria is required.[65,66] Experimental nonhuman primate studies[153] have elucidated the mechanisms of interpersonal GAS spread. The infection cycle consists of colonization, acute infection, and asymptomatic carrier phases of infection. During acute infection, GAS are present in large amounts in both the anterior nares and throat.[66] Although the acute symptomatic phase lasts only a few days, left untreated, the organism can persist for weeks in the absence of symptoms. During the asymptomatic carrier phase, bacterial burden decreases in the anterior nares and persists at lower numbers in the throat. Early studies also demonstrated that GAS in the asymptomatic carrier phase possess less hyaluronic acid capsule[126] and M protein.[123] The end result is that asymptomatic carriers are less likely to transmit the organism to close contacts than are those acutely infected. Antibiotic therapy rapidly reduces the bacterial burden and in most cases eradicates GAS from the throat. Thus, most patients are considerably less contagious within 24 hours of initiation of antibiotic therapy, reducing the risk for spread to contacts.[138]

The epidemiology and transmission of GAS skin infections is markedly different compared to throat infections. Prevalence of GAS skin infections appears to be influenced most by climate and level of hygiene. In contrast to throat infections, the peak age of incidence in impetigo and pyoderma is in children 2 to 5 years of age (i.e., preschool aged). GAS skin infections occur more frequently in hot or tropical climates[26] and, in temperate climates, infections are more common during the summer months.[46] Infection causing impetigo and pyoderma appears to be facilitated by disruption of the skin by trauma, insect bites, or preexisting skin disorders (e.g., eczema). The role of fomites and environmental contamination in the spread of GAS skin infections remains undefined.

Prospective studies on the transmission of streptococcal impetigo demonstrated that GAS initially colonize unbroken skin.[46] GAS skin colonization preceded development of impetiginous lesions by an average of 10 days.

Measures to prevent spread of GAS infections vary in their effectiveness. Spread of throat or skin infection within a family often occurs before the index case is identified and isolated or treated. In epidemic situations, especially situations involving cases of rheumatic fever or acute nephritis, a culture survey with treatment of all individuals with positive cultures (mass prophylaxis) may be indicated. Reduction of crowding, especially in sleeping quarters, seems to be an effective long-term method of minimizing the incidence of transmission of streptococcal sore throat among some groups.

In families in which persistence or recurrence of streptococcal infection is a problem, simultaneous throat culture and culture of skin lesions of all members and treatment of all who have positive results have been successful in eradicating the organism. Control of environmental contamination would be expected to have little or no influence on the spread of GAS respiratory infections,

although it possibly has an effect in controlling skin or wound infections. It also is suggested that family toothbrushes may have a role in the intrafamilial transmission of GAS. More recent guidelines have suggested, however, that performing cultures of all family members in instances in which invasive GAS infections occur is not always necessary. Because of reported instances in which secondary cases have occurred, this guideline remains controversial.[30,120]

PATHOGENESIS

Despite the numerous studies focusing on the pathogenesis of GAS infections, we understand little of mechanisms that give GAS predilection for certain body sites or why certain M serotypes are more frequently found in pharyngitis and yet others in skin infections. Infection begins with successful colonization of skin or pharyngeal epithelial surfaces. Initial interaction of GAS with epithelial surfaces is mediated by fimbriae and pili, believed to overcome the negative electrostatic forces between bacterial and host cell surfaces. More specific binding occurs through pili, M protein, hyaluronic acid capsule, and numerous fibronectin binding proteins. The complement of fibronectin binding proteins identified in GAS include proteins F1 (Prtf1) and F2 (Prtf2), SfbI, SfbII, FBP54, and others.[106]

Steps in initial colonization also require successful competition between resident flora on either the skin or pharyngeal epithelium. α-Hemolytic or viridans streptococci may interfere with throat colonization, and GAS elaborates bacteriocin-like substances that may facilitate competition.[106] Colonization of skin surfaces appears to be enhanced by physical removal of local bacterial flora.[4]

Several GAS virulence determinants participate in tissue invasion. Immune evasion is facilitated by expression of the antiphagocytic hyaluronic acid capsule, M protein, and IdeS (also known as Mac, which cleaves immunoglobulin [Ig]G bound to GAS); breakdown of neutrophil extracellular traps and host tissues by DNAses, hyaluronidases, and the cysteine protease SpeB; breakdown of chemoattractants by *S. pyogenes* cell envelope protease (SpyCEP) (cleaves IL-8), C5a peptidase (cleaves C5a); and others, including streptococcal inhibitor of complement (SIC), streptolysin O, and streptokinase. Together, these virulence factors subvert immune defenses and facilitate spread through tissues.

Recently, researchers have shed light on the in vivo molecular events that lead to invasive GAS infections. Many of the GAS virulence factors required for invasive infection are normally repressed by the CovRS two-component regulatory system. During invasive infection of serotype M1, mutations in the genes encoding the CovRS proteins result in de-repression (i.e., increased expression) of virulence factors, leading to more severe disease.[42,142] Molecular epidemiologic studies of serotype M3 GAS isolates from human pharyngitis and invasive infections demonstrated that mutations in *covS* occur at a significantly higher frequency in isolates from invasive disease in contrast to pharyngitis.[129] Whether similar de-repressing mutations occur in other serotypes is unknown.

We understand little of the mechanisms leading to early host defense against GAS infection. Although specific antibody targeted against the M protein promotes phagocytosis, it usually does not develop until 6 to 8 weeks after initial infection.[41] Rather than act during initial infection, type-specific antibody against the M protein more likely prevents reinfection by the same serologic type. Thus, in the early stages of infection, protection via phagocytosis by monocytes and polymorphonuclear leukocytes appears to be the primary mechanism of defense.

The rash and other toxic manifestations of scarlet fever have been attributed to the development of hypersensitivity to the pyrogenic toxins.[18] Toxic manifestations that have been noted in GAS toxic shock syndrome also may result from a direct influence of the pyrogenic exotoxins on lymphokines, such as tumor necrosis factor.[141] Hypersensitivity to other streptococcal products also may contribute to the manifestations of streptococcal disease.

Theories abound about the pathogenetic mechanism leading to the development of the nonsuppurative complications of streptococcal infections, acute rheumatic fever, and acute glomerulonephritis. Most of these hypotheses invoke immunologic processes in one way or another.[70,151] A major impediment toward clarifying the pathogenetic mechanism responsible for the development of nonsuppurative sequelae has been the lack of an appropriate animal model for study.

CLINICAL MANIFESTATIONS

Pharyngitis or tonsillitis caused by GAS has a brief incubation period of 12 hours to 4 days. Acute illness is characterized by abrupt onset of sore throat, malaise, fever, and headache. Children may present with nausea, vomiting, and abdominal pain. Severity can vary greatly from subclinical to a toxic appearance. Common physical findings include fever, erythema, edema, and lymphoid hyperplasia of the posterior pharynx, enlarged, hyperemic tonsils, exudate on the pharyngeal and tonsillar surfaces, and enlarged, tender lymph nodes at the mandibular angle.

Clinical manifestations generally subside spontaneously in 3 to 5 days in the absence of suppurative complications (e.g., otitis media, sinusitis, and peritonsillar abscess). Prompt antibiotic therapy (e.g., penicillin) shortens the period of fever, toxicity, and infectivity.[83,104,119] After acute streptococcal infection of the upper respiratory tract, the average latent period for glomerulonephritis is 10 days and the latent period for acute rheumatic fever is 18 days.[156]

Localized pharyngeal infection is less common in younger children, especially infants. An infantile form of streptococcal infection, streptococcal childhood fever, may be more prolonged, with persistent low-grade fever, generalized lymphadenopathy, and persistent serous nasal discharge. The term *streptococcosis* more correctly indicates the changing clinical picture with age analogous to that of tuberculosis.[116]

Infection with strains that elaborate streptococcal pyrogenic exotoxins may manifest as scarlet fever. Most commonly, scarlet fever is associated with pharyngeal

infection; however, it may also follow infection of wounds or puerperal sepsis. The characteristic rash is erythematous and finely punctate, with centrifugal spread beginning on the upper chest or trunk. The rash usually appears on the second day of illness, blanches with pressure, and spreads to cover the entire body within several hours to days. Lines of deeper red may be noted in the skinfolds of the neck, axillae, elbows, groin, and knees (Pastia's lines). The tongue may take on a strawberry appearance and become swollen and red. The skin may take on a sandpaper texture because of the occlusion of sweat glands, a particularly useful feature in dark-skinned people. Severe forms may be associated with local and hematogenous spread of the organism (i.e., septic scarlet fever) or toxemia (i.e., toxic scarlet fever). Rarely, scarlet fever may be complicated by arthritis, jaundice, and hydrops of the gallbladder. Severe manifestations are less frequent with the use of antibiotics.

Impetigo caused by GAS develops days or weeks after colonization on normal skin with an average latent period of 10 days.[46] The infection is usually painless in contrast to pharyngitis. Vesicles with minimal surrounding erythema rapidly develop into pustules and then into a thick, honey-colored crust that may persist for days or weeks. GAS impetigo does not involve the dermis, and depigmentation may be seen on healing but does not scar.

Strains of GAS that cause skin infections differ from those associated with tonsillitis and pharyngitis. The serologic types associated with skin infection tend to be higher numbered M-types because of their more recent discovery. A small number of serotypes are capable of causing both pharyngitis and skin infections.

APSGN may develop after cutaneous infection by a nephritogenic strain. Whereas rheumatic fever has not been proved to develop after skin infections with GAS, a clear association exists between GAS skin infections and rheumatic heart disease especially in Pacific populations.[109] The latent period for APSGN after skin infection is longer, 3 weeks on average, than is seen after pharyngitis (10 days).[78]

Erysipelas is a superficial streptococcal infection of the skin and sometimes adjacent mucous membranes. Three features distinguish erysipelas clinically from other forms of skin infection: (1) lesions are raised above the level of the surrounding skin, (2) a clear line of demarcation distinguishes infected from uninfected areas, and (3) lesions are a brilliant salmon-red color. Erysipelas is more common in infants and young children and most often involves the face. Lesions may be associated with wounds, an area of dermatosis (e.g., eczema), or the umbilical stump of a newborn. The cutaneous inflammation of erysipelas is often accompanied by systemic manifestations of toxicity observed in other forms of streptococcal infection.

If nothing else, GAS is notable for its ability to cause a wide range of infections. In addition to those already mentioned, suppurative complications of upper respiratory tract infection include otitis media, retropharyngeal or peritonsillar abscess, sinusitis, mastoiditis, pneumonia, and empyema. GAS are frequently isolated in cultures from peritonsillar abscesses[143] and likely act in concert with anaerobic bacteria to produce this entity.[22] Classically, acute puerperal sepsis has been associated with GAS. Infection of the skin and subcutaneous tissues (streptococcal cellulitis) may complicate burns, wounds, surgical incisions, or seemingly mild trauma. More severe infections of the deeper subcutaneous tissues and fascia with rapid spread and necrosis (necrotizing fasciitis or streptococcal gangrene) also are associated with GAS. These bacteria are a common cause of perianal cellulitis and vaginitis in children.[7,81] Subpectoral abscesses and empyemas may develop as complications of streptococcal infections of the thumb and index finger as a result of the lymphatic drainage of that part of the hand.[7] Septic complications of varicella, including varicella gangrenosa,[25,137] osteomyelitis (especially in infants),[63] hand and foot syndrome,[64] blistering distal dactylitis,[68] necrotizing fasciitis, and toxic shock syndrome, are associated with β-hemolytic streptococci.

STREPTOCOCCAL UPPER RESPIRATORY TRACT CARRIER STATE

In addition to causing a wide range of diseases, asymptomatic carriage of GAS is a common occurrence among children and adolescents. Depending on the population studied, rates of GAS carriage range from 5 to 15 percent among children,[128] a rate greatly exceeding that of any disease caused by GAS. Very early studies demonstrated that pharyngeal carriers of GAS are less dangerous to others because they harbor fewer organisms and rarely spread the organism to close contacts.[65,66] However, multiple epidemiologic studies have shown that close contacts may harbor virulent organisms in the absence of symptoms.[35,99] Thus, carriage represents a diagnostic and therapeutic dilemma for the clinician. The epidemiologic and immunologic reasons for the establishment and continuation of the carrier state are an active area of investigation.

A combination of host and bacterial factors are believed to contribute to the GAS carrier state. As opposed to true infection, in which an individual has the presence of the organism and evidence for an immunologic response, GAS carriers may harbor the organism for long periods in the absence of a host immune response.[76] Few studies have examined the bacterial or host factors that lead to persistent colonization by GAS. Bacterial studies suggest that GAS are able to internalize into epithelial cells and that internalization is associated with the presence of certain fibronectin-binding proteins.[11,102] Because penicillin does not effectively penetrate the epithelial cell, intriguingly, some have suggested that internalization of GAS into pharyngeal epithelial cells contributes to persistence despite antibiotic therapy.[77]

PEDIATRIC AUTOIMMUNE NEUROPSYCHIATRIC DISORDERS ASSOCIATED WITH STREPTOCOCCAL INFECTIONS

Pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections, referred to by the acronym PANDAS, is autoimmune disorder with

obsessive-compulsive disorder or tic disorder manifestations associated with GAS. Initially described as pediatric infection-triggered autoimmune neuropsychiatric disorders (PITANDS) by Allen and colleagues[3] in a four-patient case series and later termed PANDAS by Swedo and associates[147] in a larger study involving 50 patients, establishing the diagnostic criteria, which include the following[147]:

1. Presence of obsessive-compulsive disorder and/or a tic disorder meeting lifetime *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (DSM-IV) diagnostic criteria
2. Age at onset between 3 years of age and the beginning of puberty
3. Clinical course characterized by the abrupt onset of symptoms or by dramatic symptom exacerbations
4. Temporal association with GAS infection, diagnosed by positive throat culture and/or elevated anti-GAS antibody titers
5. Association with neurologic abnormalities such as choreiform movements or tics

This proposed disorder is currently a hypothesis, and it remains a controversial topic. Several authors believe in this disorder as a separate entity and recommend treatment and prophylaxis. Others argue that it is only a hypothesis and that further evidence with double-blind studies is needed before recommending treatment and prevention for children given a diagnosis of PANDAS.

Proposed Pathogenesis

The hypothesis for PANDAS involves several factors, including pathologic strains of GAS bacteria, host susceptibility (e.g., genetics, development, or other), and abnormal immune response.[148] A pathogenesis model has been proposed to describe the disorder (Figure 82-1).[144] Ongoing research is being conducted to understand the pathologic mechanisms involved in the PANDAS subgroup.

As part of the diagnostic criteria, temporal association with GAS infection and neuropsychiatric exacerbation is very important. It is essential to distinguish exacerbations of PANDAS resulting from GAS infection from the waxing and waning course seen in Tourette disorder and some cases of childhood-onset obsessive-compulsive disorder.[144]

According to Swedo,[144] host susceptibility is thought to result from genetic, developmental, and immunologic factors. Children in the PANDAS subgroup may have similar genetic susceptibility for poststreptococcal sequelae, as children with Sydenham chorea. Development also seems to play a role in the pathogenesis of PANDAS, because the peak age of onset of symptoms is 6 to 7 years and prepubertal onset is characteristic. PANDAS is described as an autoimmune process, and many think there are antineuronal cross-reactive antibodies similar to the autoantibodies found in Sydenham chorea.[144] These antibodies are meant to react against GAS, but in the case of PANDAS cross-react with cells in the basal ganglia.[59] Studies using MRI volumetric scans have shown bilateral enlargements of the caudate, putamen, and globus pallidus among patients in the PANDAS subgroup.[58,59]

Diagnosis

The diagnostic criteria defined by Swedo and colleagues during the description of the first 50 cases of PANDAS aimed to define a homogeneous subgroup of patients with obsessive-compulsive and tic disorders who had dramatic acute exacerbations usually following a GAS infection.[147]

These criteria as further described by Swedo and coworkers[148] are as follows:

1. *The presence of a tic disorder and/or obsessive-compulsive disorder.* The symptoms and severity required for making a diagnosis of a tic disorder and/or obsessive-compulsive disorder have been defined in the DSM-IV. The authors who established the diagnostic criteria for PANDAS limited the disorder to only tics and obsessive-compulsive symptoms to have a homogeneous patient cohort.[146] However, in the initial cohort, other psychiatric comorbidities were also found frequently, particularly attention-deficit/hyperactivity disorder (ADHD), affective disorders, and anxiety disorders. More recently, other authors propose the criteria be expanded to include related disorders such as ADHD[111] and anorexia.[140]

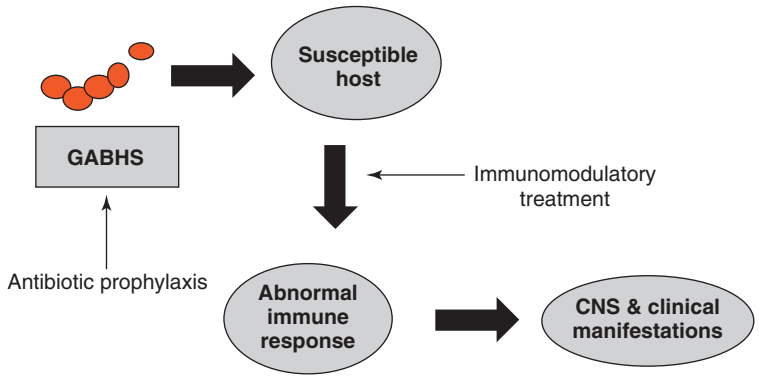

FIGURE 82-1 ■ Model of pathogenesis for PANDAS. *GABHS,* group A β-hemolytic streptococci. (See companion Expert Consult website for color version.) (Swedo SE. Pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections [PANDAS]. *Mol Psychiatry.* 2002;**7**[suppl 2]:S24.)

2. *Prepubertal age at onset, usually between 3 and 12 years of age.* The authors established this criterion based on historical data showing that rheumatic fever and other poststreptococcal sequelae are rare before the age of 3 years and after the age of 12 years. Protective serum antibodies against streptococcal infections were found in 98 percent of healthy 12-year-old controls in a study by Fischetti.[48]
3. *Abrupt symptom onset and/or episodic course of symptom severity.* Obsessive-compulsive disorder related to PANDAS usually can be distinguished from other forms of obsessive-compulsive disorder because children in the PANDAS subgroup typically have a sudden onset of symptoms, reaching a peak in 24 to 48 hours, whereas in non-PANDAS obsessive-compulsive disorder, a more gradual onset of obsessions and compulsions occurs. In a similar manner, children with PANDAS who have tics have more intense, frequent motor and vocal tics than those with a simple isolated, intermittent tic not associated with PANDAS.[146]
4. *Temporal association between symptom exacerbations and streptococcal infections.* Based on observational clinical studies, exacerbations of neuropsychiatric symptoms begin within 7 to 14 days after an infection with GAS and usually occur simultaneously.[146] However, because streptococcal infections are so common during childhood, a single positive throat culture or elevated antistreptococcal antibody titer is not enough evidence to say that a child's neuropsychiatric symptoms are associated with a streptococcal infection. For a child to fit this diagnostic criterion, prospective evaluation and documentation of at least two episodes of neuropsychiatric symptoms that correlate with streptococcal infections should be done, as well as documentation of evidence of negative throat cultures or antibody titers when the patient goes into remission of neuropsychiatric symptoms.
5. *Presence of neurologic abnormalities during periods of symptom exacerbation.* Choreiform movements seen in PANDAS patients are small, jerky movements that occur in an irregular and arrhythmic pattern in different muscles,[147] described as fine piano-playing movements of the fingers. These movements are distinct from the movements of Sydenham chorea because choreiform movements are not present at rest and must be elicited through stressed posture, and in the case of chorea the movements are constantly present and increase with unrelated voluntary movements.[146] Patients with a diagnosis of rheumatic fever, including chorea, should be excluded from the PANDAS subgroup.[147] Children considered to have possible PANDAS syndrome who have symptoms suggestive of streptococcal infection should undergo evaluation for GAS infection. Rapid streptococcal antigen tests backed by throat culture if negative should be obtained. In patients who have negative throat cultures, ASO and anti–DNAse B titers could be obtained if the onset of PANDAS was at least 4 to 6 weeks earlier. With acute exacerbations of tics or obsessive-compulsive disorder symptoms, patients should be reevaluated for an acute infection resulting from GAS.[145]

A diagnostic marker present in children with rheumatic fever—D8/17—has been postulated to also identify children with PANDAS,[148] but its use in diagnosis of PANDAS remains controversial.[131]

Treatment

All patients who have an acute GAS infection should receive appropriate antibiotic therapy, usually with penicillin, because it remains the drug of choice. Treatment of the streptococcal infection has been noted by some authors to improve or cure the neuropsychiatric symptoms of PANDAS. A small prospective study[101] of 12 patients showed resolution of symptoms of new-onset obsessive-compulsive disorder, anxiety, and tics within an average of 14 days after starting treatment with an antibiotic (i.e., penicillin, amoxicillin, amoxicillin/clavulanate, or a cephalosporin). Every recurrent episode of PANDAS was associated with a GAS infection, and all patients with recurrences showed improvement after treatment with antibiotics.[101] However, this was a small study, not a double-blind, randomized controlled trial.

Children with a significant tic disorder or obsessive-compulsive disorder should receive appropriate psychiatric medications as necessary. Medications used in the treatment of tics include α agonists. For the treatment of obsessive-compulsive disorder, medications used include classic or atypical antipsychotics and selective serotonin reuptake inhibitors. Cognitive behavioral therapy also may be beneficial in the treatment of obsessive-compulsive disorder. These treatments are commonly used in tics and obsessive-compulsive disorder not related to PANDAS and also have been used for treatment of neuropsychiatric symptoms in patients given a diagnosis of PANDAS.[84]

Immunomodulators have been used in therapeutic trials based on the proposed model of immunologic dysfunction. One study reported benefits in patients fulfilling criteria for PANDAS in the group treated with plasma exchange and in the group treated with intravenous immunoglobulin (IVIG).[110] However, this study was limited by small sample size, highly selective recruitment, and limited comparisons with controls. In addition, nearly two thirds of patients receiving active treatment experienced adverse effects.[110] Currently, the National Institute of Mental Health recommends that plasma exchange and IVIG be reserved only for patients involved in approved research protocols.[103]

Prevention

The pathogenesis of PANDAS has been proposed to be an autoimmune process similar to rheumatic fever and Sydenham chorea.[144] Penicillin is recommended to prevent recurrences of the latter two conditions. A few clinical trials have been performed to determine whether antibiotic prophylaxis to prevent GAS infection can help reduce the neuropsychiatric morbidity seen in PANDAS and prevent future exacerbations. In a placebo-controlled,

double-blind crossover study involving 37 children with PANDAS published in 1999, penicillin failed to prevent streptococcal infections and no differences were found in the severity of obsessive-compulsive disorder and tics between the two phases.[53] A double-blind, randomized controlled trial of 23 children published in 2005 compared penicillin (as "active placebo") and azithromycin in the prevention of GAS infection and exacerbation of PANDAS. Both penicillin and azithromycin prophylaxis were found to be effective in the prevention of recurrent GAS infections and decreased the neuropsychiatric symptom exacerbations in the PANDAS subgroup.[139] However, this study had a small sample size and lacked an inactive placebo group. At present, antibiotics are recommended only to treat the acute GAS infection and are not indicated for the prophylaxis of PANDAS recurrences.[145,146]

Arguments Against PANDAS

Considerable controversy still exists surrounding the topic of PANDAS.[92,135] At this moment, it remains a hypothesis, and many argue that sufficient evidence is lacking to support PANDAS as a diagnostic entity.[132,133] For instance, a recent prospective longitudinal study comparing PANDAS and non-PANDAS cases of Tourette syndrome and obsessive-compulsive disorder did not show a temporal relation between exacerbation of neuropsychiatric symptoms and a GAS infection in the PANDAS group (a few exacerbations of symptoms were associated with a GAS infection in the control group).[87] An argument has even been proposed that the initial cases with choreiform movements could represent missed cases of chorea.[84] The authors in a study showing failure of immune markers to correlate with clinical exacerbations in PANDAS question the autoimmune pathogenesis of the disorder.[134] Similar concerns were raised by a study that failed to show differences in serum autoantibodies between PANDAS and Tourette syndrome (controls).[100]

Further research is needed to establish PANDAS as a clinical entity, to further describe the pathogenesis of the disease, demonstrate disease in animal models, and determine its appropriate treatment and prevention in randomized double-blind, placebo-controlled trials.

Updates to PANDAS Definition

Because the concept of PANDAS has generated much controversy and conflict regarding the scientific evidence to support this hypothesis, many researchers and clinicians have recently proposed elimination of the diagnosis of PANDAS in favor of a broader diagnostic category.[135] Many other infectious agents in addition to GAS have been suggested as possible causes of acute neuropsychiatric symptoms, including *Borrelia burgdorferi*, herpes simplex virus, varicella-zoster virus, and *Mycoplasma pneumoniae*.[135,149] Singer and colleagues[135] proposed moving away from PANDAS and using the term *childhood-onset acute neuropsychiatric symptoms (CANS)*. This definition requires only an acute, dramatic onset of symptoms, but the authors emphasize the importance of a thorough history, physical examination, and differential diagnosis to search for a specific etiology and treat accordingly.

Even though debate has continued about the role of GAS in the pathogenesis of PANDAS, experts on either side still agree on the existence of a subgroup of children with obsessive-compulsive disorder with an abrupt onset of symptoms.[149] To the PANDAS controversy, a group of clinicians and scientists met in July, 2010 for a workshop on PANDAS. During this workshop, modifications to the PANDAS criteria were made to broaden the spectrum of acute-onset obsessive-compulsive disorder and related neuropsychiatric disorders. It was decided that the new syndrome should not exclude cases with postpubertal onset. One of the names proposed was CANS, but it was not favored because childhood onset would exclude adolescents.[149] The consensus of the workshop members was to use the term *pediatric acute-onset neuropsychiatric syndrome (PANS)* because it would extend the age to at least 18 years (and 21 years by some definitions).[149] The three PANS criteria, as defined by Swedo and colleagues,[149] are (1) abrupt, dramatic onset of obsessive-compulsive disorder or severely restricted food intake; (2) concurrent presence of additional neuropsychiatric symptoms, with similarly severe and acute onset, from at least two of the following seven categories: (a) anxiety; (b) emotional lability and/or depression; (c) irritability, aggression, and/or severely oppositional behaviors; (d) behavioral (developmental) regression; (e) deterioration in school performance; (f) sensory or motor abnormalities; and (g) somatic signs and symptoms, including sleep disturbances, enuresis, or urinary frequency; and (3) symptoms not better explained by a known neurologic or medical disorder, such as Sydenham chorea, systemic lupus erythematosus, Tourette disorder, or others. Patients thought to have PANS should undergo a comprehensive workup, which may include magnetic resonance imaging, lumbar puncture, or electroencephalogram, if necessary, to rule out other neuropsychiatric disorders.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

A combination of clinical appearance, identification of the organism, and epidemiologic findings are used to confirm the probability of pharyngitis or tonsillitis caused by GAS. Multiple etiologic agents may be responsible for pharyngitis, compounding the difficulty in the diagnosis of GAS as the cause.[2] Pharyngitis, characterized by the triad of fever, sore throat, and pharyngeal inflammation, may be caused by multiple viruses, *Corynebacterium diphtheriae*, *Neisseria gonorrhoeae*, *Fusobacterium necrophorum*, and groups C and G streptococci, in addition to GAS. The clinical syndrome associated with *Arcanobacterium hemolyticus* can be very similar to that associated with GAS.

Multiple clinical prediction rules have been developed to aid in the diagnosis of GAS pharyngitis. Acute pharyngitis attributable to GAS may be aided by the use of clinical scoring systems.[32,94,95] These prediction rules are limited because the signs and symptoms of many viral causes of acute pharyngitis overlap with infection caused

by GAS. The rules are best at identifying patients with a low probability for GAS infection. Thus, the guidelines from the Infectious Diseases Society of America (IDSA), the Committee on Infectious Diseases of the American Academy of Pediatrics (AAP), and the American Heart Association recommend confirmation of GAS infection by rapid antigen detection testing, throat culture, or both.[5,16,38] Clinical manifestations that are most suggestive of GAS pharyngitis include the scarlatiniform rash, excoriated nares (especially in infants), tender (may or may not be enlarged) anterior cervical lymph nodes, and a history of close contact with a known case of GAS infection. Cough, hoarseness, or conjunctivitis make the diagnosis of streptococcal pharyngitis far less likely. Exudative pharyngitis in infants usually is nonstreptococcal in etiology.

Empirical therapy based on the use of predication rules has been implicated in the overuse of antibiotics for the treatment of pharyngitis.[95] A study on the effectiveness of these strategies showed that empirical treatment is a reasonable strategy for those least likely to have GAS pharyngitis but microbiologic confirmation was the most effective and least expensive when considering all factors.[105] In addition, in 78 percent of cases, physicians did not adhere to any guideline, leading to overuse of antibiotics for the treatment of pharyngitis.[88] More recently, it was shown that incorporating local GAS prevalence rates into prediction rules reduced the number of missed cases and the misuse of antibiotics where they were unnecessary.[47]

Cultures may yield invalid results unless they are obtained and processed carefully. Assaying for the presence of GAS by throat culture on sheep blood agar plate, as first described by Breese and Disney,[20] has been accepted practice for diagnosing streptococcal pharyngitis for over 50 years. Ideally, specimens should be obtained from bilateral tonsillar surfaces and the posterior pharynx while avoiding the mouth and other surfaces of the pharynx. Impetiginous lesions should be cleansed with alcohol, and the vesicle should be punctured or the crust lifted by a sterile needle so that the moist base or purulent material can be touched with the swab.

Numerous rapid techniques for direct identification of GAS from the upper respiratory tract are available commercially. Rapid antigen detection testing has become more readily available and in some instances has been reported to equal or exceed the sensitivity and specificity of throat culture. Rapid testing may lead to more timely treatment and, in so doing, can reduce the spread of GAS, reduce time missed from school or work, and minimize suppurative and nonsuppurative sequelae of GAS. The original rapid antigen detection tests were based on the detection of GAS cell wall carbohydrate antigen by enzyme immunoassays. Subsequently, optical immunoassays became commercially available and initially were thought to provide greater sensitivity than the previous generation of tests. Owing to differences in the manufacturer, test, and study design, the sensitivities and specificities of all rapid antigen detection tests are essentially the same.[55] Newer assays employ molecular biology methods to detect DNA specific to GAS by chemiluminescence or real-time polymerase chain reaction, but are restricted because of the need to batch specimens and the specialized equipment required. The sensitivity of rapid antigen detection tests is 70 to 90 percent, in contrast to blood agar plate culture, with a specificity of approximately 95 percent.[57] Of importance, rapid antigen detection test specimens must be collected in a manner similar to specimen collection for blood agar plate culture. Swabs obtained from the mouth and subjected to rapid antigen detection testing have a sensitivity of less than 20 versus 80 percent for those obtained properly from the posterior pharynx and tonsils.[50] The current recommendation is that a negative rapid antigen detection test be confirmed by blood agar plate culture for all children.[5,16,38]

In addition to microbiologic and rapid antigen detection tests, immunologic tests for the presence of GAS frequently are used to assist in the diagnosis of GAS infection. The ASO test is used most frequently.[130] However, streptolysin O is also produced by groups C and G streptococci; thus, the test is not specific for GAS infection. Patients with skin infections caused by GAS may have a feeble response to streptolysin O.[79] In contrast, anti-DNAse B and antihyaluronidase are more reliable after either skin or throat infections.[79]

Streptozyme agglutination, another antibody test, is based on antibody agglutination of erythrocytes coated with a mixture of streptococcal extracellular antigens. Peak titers for an immune response as measured by the Streptozyme test appear within the first 7 to 10 days after infection,[107] whereas ASO (3 to 6 weeks) or anti-DNAse B (6 to 8 weeks) do not peak until later. Recent studies indicate that the initial titer of either may not be indicative of infection and that elevation after measurement of sequential titers is more accurate.[75] Given the delay in antibody response and need for sequential measurement, ASO anti-DNAse B should not be used to determine acute infection.

TREATMENT

GAS remain universally susceptible to penicillin in vitro. Oral penicillin V and intramuscular benzathine penicillin are the drugs of choice for the treatment of GAS, except in patients with a penicillin allergy.[57] The advantages of penicillin include a narrow spectrum of activity, proved efficacy, and low cost.[57]

Initial studies on the efficacy of penicillin for the primary prevention of acute rheumatic fever were conducted with military recruits in the 1950s.[40,157,158] Initial studies involved the use of injectable penicillin suspended in either sesame oil or peanut oil, and they showed therapeutic penicillin concentrations in serum for 9 to 10 days.[158] Later studies found an equal bacterial eradication rate of 10 days with either oral penicillin G or injectable benzathine penicillin.[157] Oral penicillin remains the first-line therapy because benzathine penicillin G is associated with pain and increased risk for allergic reactions.[112] However, in certain situations in which adherence to regimen or follow-up is not possible, intramuscular benzathine penicillin is preferred.

The established regimen is 10 days of penicillin V treatment or a single dose of benzathine penicillin to

TABLE 82-1 **Primary Prevention of Rheumatic Fever (Treatment of Streptococcal Tonsillopharyngitis)***

Agent	Dose	Mode	Duration	Rating
Penicillins				
Penicillin V (phenoxymethyl penicillin)	Children: 250 mg 2-3 times per day for ≤27 kg (60 lb); children >27 kg (60 lb), adolescents, and adults: 500 mg 2-3 times per day	Oral	10 days	IB
	or			
Amoxicillin	50 mg/kg/day (maximum 1 g)	Oral	10 days	IB
	or			
Benzathine penicillin G	600,000 U for patients ≤27 kg (60 lb); 1,200,000 U for patients >27 kg (60 lb)	Intramuscular	Once	IB
For individuals allergic to penicillin				
Narrow-spectrum cephalosporin† (cephalexin, cefadroxil)	Variable	Oral	10 days	IB
	or			
Clindamycin	20 mg/kg/day divided in 3 doses (maximum 1.8 g/day)	Oral	10 days	IIaB
	or			
Azithromycin	12 mg/kg/day (maximum 500 mg)	Oral	5 days	IIaB
	or			
Clarithromycin	15 mg/kg/day divided in 2 doses (maximum 250 mg bid)	Oral	10 days	IIaB

From Gerber MA, Baltimore RS, Eaton CB, et al: Prevention of rheumatic fever and diagnosis and treatment of acute streptococcal pharyngitis: a scientific statement from the American Heart Association Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee of the Council on Cardiovascular Disease in the Young, the Interdisciplinary Council on Functional Genomics and Translational Biology, and the Interdisciplinary Council on Quality of Care and Outcomes Research—endorsed by the American Academy of Pediatrics. *Circulation* 119:1544, 2009.

Rating indicates classification of recommendation and level of evidence (LOE) (e.g., IB indicates class I, LOE B)

*For other acceptable alternatives, see text. The following are not acceptable: sulfonamides, trimethoprim, tetracyclines, and fluoroquinolones.

†To be avoided in those with immediate (type I) hypersensitivity to penicillin.

prevent acute rheumatic fever.[17,57] The most recent American Heart Association guidelines for the prevention of rheumatic fever and treatment of acute streptococcal pharyngitis[57] recommend dosages of penicillin V 40 mg/kg (not to exceed 750 mg for those weighing <27 kg) per 24 hours given in three equally divided doses for 10 days. The dose recommended for most children is 250 mg twice per day, and the dose usually recommended for adolescents and adults is 500 mg two or three times per day (Table 82-1).[57] Penicillin V is preferred to penicillin G because it is more resistant to gastric acid. Although penicillin V is the recommended drug, many physicians prescribe amoxicillin because of its improved taste. Recently, an oral time-released formulation of amoxicillin was approved by the U.S. Food and Drug Administration (FDA) for once-daily therapy for patients 12 years of age and older.[57]

For patients with a penicillin allergy, a 10-day oral course of a narrow-spectrum cephalosporin (e.g., cefadroxil or cephalexin) is recommended. Some studies have shown that 10 days of an oral cephalosporin is superior to a 10 day-course of oral penicillin.[61,114] Other studies suggest that treatment with 5 days of an oral broad-spectrum cephalosporin is comparable to treatment with 10 days of oral penicillin in the eradication of GAS tonsillopharyngitis.[57,115] However, at present these shorter regimens have not been approved by the FDA. In the past, erythromycin was the drug of choice for penicillin-allergic patients, but it has been replaced by newer medications because they have lower rates of gastrointestinal side effects and easier administration regimens.[33,51,57] In patients with an immediate hypersensitivity (anaphylactic type) to penicillin, cephalosporins should be avoided, and macrolides (i.e., erythromycin or clarithromycin), azithromycin (an azalide), or clindamycin (a lincosamide) should be used. Recommended doses are shown in Table 82-1.

Macrolide resistance has been documented in many countries and remains an ongoing concern for the treatment of GAS infections.[51,89] Although erythromycin-resistant organisms were found in the 1950s, it was not until the 1970s that clinically significant macrolide resistance was noted.[51] Resistance to macrolides occurs by one of two mechanisms: an active efflux pump (M phenotype) related to enzymes encoded for by *mef* genes or ribosomal target site modification by methylation (*erm* genes), which causes coresistance to macrolide, lincosamide, and streptogramin (MLS) antibiotics (MLS phenotype).[89] Countries such as Japan, Finland, Italy, and the United States have reported treatment failures resulting from macrolide resistance.[51] A study in Finland[127] reported a decrease in the use of macrolide antibiotics from 2.40 defined daily doses per 1000 inhabitants per day in 1991 to 1.38 in 1992, after national recommendations were

made to reduce the number of macrolides prescribed for respiratory and skin infections. This resulted in a decrease in macrolide resistance from 16.5 percent in 1992 to 8.6 percent in 1996.[127] Although the rate of resistance in the United States is relatively low in contrast to much of the rest of the world, a recent U.S. multicenter surveillance study[62] found an overall adjusted rate of macrolide resistance in GAS of 5.2 percent. This represents a near twofold increase from rates reported in the United States in the 1990s. In recent years, U.S. macrolide resistance rates have ranged between 5 and 8 percent.[5] To avoid further increases in macrolide resistance that may result in treatment failures and acute rheumatic fever, some experts recommend that macrolide antibiotics be reserved for the treatment of GAS infections in patients with the anaphylactic type of penicillin allergy.[89]

Certain broad-spectrum antibiotics should not be used against GAS. Tetracycline has a high prevalence of resistance and thus is not recommended. Sulfonamides and trimethoprim-sulfamethoxazole should be avoided because they do not eradicate GAS from the pharynx. Ciprofloxacin has limited activity against GAS and therefore should not be used. Newer fluoroquinolones, such as levofloxacin and moxifloxacin, have shown in vitro activity against GAS but should not be used because they are expensive and provide an excessive broad-spectrum activity.[37,54,57]

Even though penicillin remains the drug of choice in the treatment of GAS, penicillin treatment failures of 20 to 40 percent or higher have been reported in the literature.[113] It has been documented more often after oral penicillin than after benzathine penicillin.[45] Possible explanations for penicillin treatment failures include lack of compliance, penicillin tolerance, and carrier state.[57,113] Other considerations that have been proposed include copathogens in the pharynx[60,113,114,136] and antibiotic suppression of immunity.[21,57,159] Some authors have suggested that certain β-lactamase organisms such as *Staphylococcus aureus*, *Haemophilus influenzae*, *Moraxella catarrhalis*, and anaerobes may be present in the pharynx during a GAS infection and inactivate penicillin. They argue that this may be one of the reasons for the superiority of β-lactamase stable antibiotics in cases of penicillin failures.[115] Studies from the 1940s and 1950s documented that antibiotics given shortly after onset of symptoms (within 24 to 48 hours) could suppress the immune response to the infection.[21,159] Other studies did not show a difference whether treatment was started early or delayed for 48 hours.[56] It has been shown that penicillin therapy is effective in preventing rheumatic fever when started within 9 days after the onset of illness.[29,57] Delaying therapy for 24 to 48 hours until culture results are known does not increase the risk for rheumatic fever.[57] However, therapy should not be delayed in patients who appear toxic or are severely ill.

At present, recommendations in the management of GAS pharyngitis in children include obtaining a streptococcal rapid antigen detection test, with initiation of treatment when positive. Negative rapid antigen detection tests should be backed by a throat culture. Follow-up cultures in patients treated for GAS are no longer routinely recommended and should be performed only in those who remain symptomatic, have recurrence of symptoms, or have a history of rheumatic fever.[17,57] Children with recurrence of GAS pharyngitis symptoms after completing a 10-day course of a recommended oral antimicrobial agent can be retreated with the same antimicrobial agent, given an alternative oral drug, or given an intramuscular dose of penicillin G benzathine, especially if noncompliance is suspected. Alternative drugs include a narrow-spectrum cephalosporin, amoxicillin-clavulanate, clindamycin, a macrolide, azalide, or penicillin plus rifampin.[5,54]

Individuals found to have positive rapid antigen detection test or throat cultures without clinical evidence of infection or rise in antistreptococcal titers are considered chronic streptococcal carriers and do not need to be treated with antibiotics. However, because it may be difficult to distinguish a carrier state from true GAS infection when a viral upper respiratory tract infection develops in a carrier, appropriate antibiotics should be prescribed to any patient with acute pharyngitis and evidence of GAS from a positive rapid antigen detection test or throat culture.[57]

Although guidelines from the American Heart Association exist for the treatment of GAS tonsillopharyngitis, no official guidelines exist for the treatment of streptococcal impetigo. For patients with a few lesions, topical therapy with mupirocin or retapamulin ointment may be useful for limiting person-to-person spread and for eradicating localized disease.[5] In more severe cases with multiple lesions or with nonbullous impetigo in multiple family members, child care groups, or athletic teams, impetigo should be treated with systemic antimicrobials.[5] Oral or parenteral penicillin may be used in the same doses as those for streptococcal infections. Regimens with first-generation cephalosporins or macrolides should be used for penicillin-allergic patients. With the increase in skin and soft tissue infections resulting in methicillin-resistant *Staphylococcus aureus* (MRSA), obtaining appropriate cultures and treating with antibiotics to cover this possible pathogen also must be considered.

Although treatment with penicillin has been shown to prevent the development of rheumatic fever, no definitive evidence exists that antimicrobial therapy after treatment of streptococcal skin infections prevents acute poststreptococcal glomerulonephritis.[5]

Otitis media and cervical adenitis resulting from GAS can be treated with the same regimens used for the treatment of streptococcal pharyngitis. Systemic parenteral antimicrobial therapy is indicated for severe infections, such as septicemia, pneumonia, endocarditis, meningitis, arthritis, osteomyelitis, erysipelas, necrotizing fasciitis, neonatal omphalitis, and streptococcal toxic shock syndrome. Treatment often is prolonged (2 to 6 weeks).[5] In the case of toxic shock syndrome, clindamycin is also recommended because it is a protein-synthesis inhibitor and can neutralize bacterial toxins. Drainage of any lesions is warranted. IVIG can be considered as adjunctive therapy for GAS-related toxic shock syndrome or necrotizing fasciitis if the patient is severely ill.[5]

PREVENTION

Treatment of GAS pharyngitis with antimicrobials aims to prevent rheumatic fever through primary prevention. Prevention of recurrence of rheumatic fever (secondary prevention) requires continuous antimicrobial prophylaxis (see Chapter 29). A meta-analysis of 10 trials on primary prevention of rheumatic fever that were conducted in the United States during 1950 to 1961 revealed that, although the methodology of the studies was poor, administration of antibiotics in patients with GAS infection reduced the risk for acute rheumatic fever by nearly 70 percent.[121] A subgroup analysis showed that the risk reduction was 80 percent when treated with intramuscular penicillin.[121]

Although the incidence of acute rheumatic fever has decreased in the developing world for the past 50 years, outbreaks in the community and the military continue to occur, and acute rheumatic fever remains a major cause of morbidity and mortality in the developing world.[36] Current strategies for disease prevention include infection-control measures such as isolation, appropriate hygiene measures for postpartum and postsurgical patients, and establishing nationwide surveillance systems.[36] During episodes of epidemic GAS infections, mass prophylaxis with penicillin, particularly intramuscular benzathine penicillin G, has been shown effective.

Children in the outpatient setting being treated for a GAS infection may return to daycare or school after 24 hours of treatment. For hospitalized children, droplet precautions are recommended for GAS pharyngitis or pneumonia until 24 hours after initiation of appropriate antimicrobial therapy. In the case of burns with secondary GAS infection and extensive or draining cutaneous infections that cannot be covered by dressings, patients should remain in contact precautions for at least 24 hours after the start of appropriate therapy.[5] Asymptomatic household contacts do not require diagnostic evaluation or chemoprophylaxis, unless exposure occurs during outbreaks or the contacts are at higher risk for developing sequelae of infection.[5]

In certain cases of GAS pharyngitis refractory to treatment, tonsillectomy has been performed, but at present, data are insufficient to recommend routine tonsillectomy as part of the management of GAS pharyngeal infections.

The persistence of acute rheumatic fever and its associated morbidity and mortality, especially in the developing world, despite the use of antimicrobials, has led to intensive research in vaccine development against GAS. However, despite more than 70 years of research, a commercial vaccine is still not available.[36] One of the main concerns for development of vaccines based on the M protein was the possibility of causing autoantibodies that could cross-react with the heart, skeletal muscle, brain, and glomerular basement membrane tissues.[33,36] Early studies in the 1960s found a higher incidence of acute rheumatic fever in those vaccinated than in the general population.[33] Two vaccines have been evaluated in clinical trials and found to be well tolerated and safe. One of these is a 26-valent vaccine including 86 percent of the serotypes causing GAS pharyngitis, which could prevent 49 to 63 percent of invasive GAS infections among children and 43 to 50 percent among elderly individuals, with similar decreases in the number of deaths.[108] It was tested in 30 healthy adults in the United States and was found to be immunogenic and safe.[36] However, because of the geographic and temporal differences in M-types between countries, this vaccine may not be as effective in other countries, such as Japan, Ethiopia, or New Zealand.[36,124] Other components of GAS have been under investigation as potential candidates in the development of a vaccine. These include carbohydrate antigens, adhesins, C5a peptidase, and the GAS pilus.[33] Mucosal vaccines to GAS are also under investigation because mouse studies have found induction of specific IgA production during intranasal administration of vaccine, along with IgG production in serum.[33] Further research is needed in GAS vaccine development, with a goal of vaccines that may be useful globally.

GROUP C AND GROUP G STREPTOCOCAL INFECTIONS

Organisms

The β-hemolytic streptococci include GAS, *Streptococcus agalactiae* (group B streptococcus), and groups C, F, and G streptococci, based on the β-hemolysis they produce on blood agar plates. In addition, *Streptococcus milleri* organisms (*Streptococcus anginosus*, *Streptococcus constellatus*, and *Streptococcus intermedius*) may have variable hemolysis, and approximately one third have group A, C, F, or G antigens.[6] Depending on their colony size, strains with either the group C or group G Lancefield carbohydrate antigens can be divided into small or large colony–forming strains. The small colony–forming strains (<0.5 mm in diameter) belong to the *S. anginosus (S. milleri)* group, which are considered part of the viridans group streptococci. Large colony–forming strains (>0.5) are considered true group C or group G streptococci (GCS and GGS, respectively).[23]

Lancefield group carbohydrate antigen and hemolytic reaction have been classically used for the identification of streptococci. However, streptococcal taxonomy has been significantly revised recently because of overlap between species. Currently, three species of groups C and G have been described that are pathogenic in humans: *Streptococcus dysgalactiae*, *Streptococcus equi* subsp. *zooepidemicus*, and *Streptococcus canis*.[23]

Group C streptococci (GCS) are catalase-negative, aerobic, facultatively anaerobic, coprophilic organisms. They are usually β-hemolytic, although all types of hemolysis have been seen with GCS. The group C antigenic determinant in their cell wall is rhamnose-*N*-acetylgalactosamine. Four species that possess this antigenic determinant were defined based on their ability to ferment various carbohydrates (*Streptococcus equisimilis*, *S. zooepidemicus*, *S. equi*, and *S. dysgalactiae*). Revision of the taxonomy after new research based on genetic studies (such as 16S RNA analysis) has shown that there are actually two GCS species, S. *dysgalactiae* and *S. equi*, each with two subspecies.

Group G streptococci (GGS) typically show β-hemolysis on blood agar plates. They are facultative anaerobes. The group G antigenic determinant in their cell wall is L-rhamnose. The majority of GGS infections in humans are due to *S. dysgalactiae* subsp. *equisimilis*, but a few infections with *S. canis* have been reported.

Some of the same virulent factors found in GAS have been shown to be present in GCS and GGS, such as M protein, streptolysin, hyaluronidase, and C5a peptidase.[67,71,90,125]

Epidemiology

GCS and GGS in humans may colonize the skin, oropharynx, gastrointestinal tract, and vagina.[6] In addition, GCS have been cultured from the umbilicus of asymptomatic newborns and from routine puerperal vaginal samples. Classically, these streptococcal groups have been thought to be a rare cause of infection in humans. They are common causes of animal infections, and many humans infected with these streptococci report animal contact. GCS and GGS have been known to cause foodborne outbreaks of pharyngitis.[6]

The classification and nomenclature of GCS and GGS has changed significantly, however, and clinical specimens are rarely identified to the species level by clinical laboratories, making it difficult to know the true burden of these infections. The first population-based study of the epidemiology and burden of invasive disease resulting from non–group A or B β-hemolytic streptococci (NABS) in the United States over a 2-year period was published in 2009.[23] According to this study, the majority of patients (87%) with invasive disease had underlying comorbid conditions, as has been previously reported.[67,90] *S. dysgalactiae* subsp. *equisimilis* was the most common organism (80%) among patients with invasive disease. However, the data for individuals younger than 20 years of age (6% of the patients) was different. Only 23 percent of the younger patients had underlying conditions, with asthma as the most common comorbidity. Isolates from pediatric patients were most often group F (40%), followed by group G (36%) and group C (24%). One very important finding of this study is that the burden of NABS infection in the United States during the study period was similar to that caused by invasive GAS infection: 3.2 cases/100,000 population and 2.89 cases/100,000, respectively.[23] A 6-month surveillance study published in Argentina in 2005 reported similar findings that most of the GCS and GGS *S. dysgalactiae* subsp. *equisimilis* infections occurred in adults and that diabetes was frequently seen as an underlying condition.[90]

Clinical Manifestations

GCS and GGS may cause invasive disease in infants, older children, and adults. The principal clinical manifestations of these organisms are upper and lower respiratory tract infections, septicemia, pneumonitis, skin and soft tissue infections, septic arthritis, osteomyelitis, meningitis with a parameningeal focus, brain abscess, puerperal and neonatal sepsis, peritonitis, and endocarditis.[6,8,154]

Pharyngitis caused by GCS and GGS has symptoms similar to those seen with GAS pharyngitis. GCS are a relatively common cause of acute pharyngitis among college students and among adults seen in the emergency department.[57] Between 1 and 18 percent of asymptomatic pharyngeal carriers of GCS may be found in temperate climates, with higher percentages in the tropics. Similarly, between 1 and 23 percent of asymptomatic pharyngeal carriers of GGS may live in temperate climates. In addition, foodborne episodes of pharyngitis caused by GCS and GGS have been documented.[6] These epidemic outbreaks may occur after consumption of contaminated products, such as unpasteurized cow's milk.

Acute rheumatic fever has not been documented as a complication of either GCS- or GGS-associated pharyngitis.[57] Acute glomerulonephritis has been reported as a complication of GCS-associated pharyngitis, but a causal relationship has not been established.

Rare neonatal GGS and GCS infections have been reported, with symptoms similar to those of early-onset GBS sepsis.

GCS and GGS have been reported as a rare cause of skin and soft tissue infections. A report reviewing all cases of septic arthritis caused by β-hemolytic streptococci at Stanford University Medical Center in California from 1985 through 1996 found that 40 percent of cases were due to GAS, 30 percent to GBS, and 30 percent to GGS. No cases caused by GCS were reported during that time. Presence of infected prosthetic implants was found in the majority of patients with septic arthritis caused by GGS.[125] Rare cases of deep soft tissue infection resulting from GGS, such as necrotizing fasciitis, localized pyomyositis, and even myositis with subsequent fatal streptococcal toxic shock syndrome have been reported in the literature.[154]

Streptococcal toxic shock syndrome typically has been associated with GAS, but recent case reports have shown cases resulting from GCS and GGS infection. Most of the cases have been due to *S. dysgalactiae* subsp. *equisimilis*, but a recent study from Japan[67] reported the first case of streptococcal toxic shock syndrome caused by *S. equi* subsp. *zooepidemicus*. Because most clinical isolates of GCS and GGS are β-hemolytic and some isolates are susceptible to bacitracin, some GCS and GGS may have been misidentified as GAS if Lancefield serologic testing was not performed.[67] Therefore, the true rates of these diseases may be underestimated. Patients with GAS-related streptococcal toxic shock syndrome usually are previously healthy, whereas patients with infections caused by GCS and GGS, including streptococcal toxic shock syndrome, usually have underlying conditions such as diabetes mellitus, cardiopulmonary disease, malignancy, collagen disease, liver failure, or renal failure.[67]

Although rare, some cases of bacterial endocarditis may be caused by GCS and GGS infections. The mortality rates for these infections are high, reported as 41 percent for GCS and 35 percent for GGS, although the overall mortality rate of infective endocarditis by β-hemolytic streptococci was much lower (12.9%) in a questionnaire study by Baddour and the IDSA's Emerging Infections Network (EIN) members.[10]

Treatment

Penicillin remains the treatment of choice for GCS and GGS infections.[8,122] Penicillin-tolerant strains have been reported in laboratory findings, but the clinical significance is not known.[8,122] For most GCS and GGS infections, treatment with penicillin G alone is adequate. Other antimicrobial regimens that have been shown to work in vitro include penicillin with gentamicin, other β-lactam agents such as cephalosporins, vancomycin, and vancomycin with rifampin.[6] Resistance to macrolides, tetracycline, and chloramphenicol have been reported in the literature.[23,67,90] A few isolates of GCS and GGS *S. dysgalactiae* subsp. *equisimilis* have shown high-level resistance to aminoglycosides.[23,90]

Guidelines for the treatment of endocarditis caused by GCS and GGS have not been established because these infections are infrequent. Usually, high-dose penicillin G is recommended for 4 to 6 weeks. Some experts recommend the addition of gentamicin to penicillin for at least the first 2 weeks of therapy.[10]

CHAPTER 83

Group B Streptococcal Infections

Pia S. Pannaraj • Carol J. Baker

HISTORY

Group B *Streptococcus*, or *Streptococcus agalactiae*, was isolated first by Nocard in 1887[252] and for decades was recognized as a cause of bovine mastitis[241] but not human infection. Serologic techniques for differentiating β-hemolytic streptococci were developed by Lancefield,[191] who also described isolation of group B streptococci (GBS) from parturient women in 1935.[193] In that same year, Congdon[84] included one fatal puerperal case of GBS sepsis and pneumonia in a report of streptococcal infections associated with childbirth. The significance of this organism as a human pathogen was reported first by Fry[127] in 1938, who described three cases of fatal puerperal sepsis. GBS infections continued to be reported sporadically until the 1960s, when maternal and neonatal infections increasingly were ascribed to this pathogen.[69,109,161] In the 1970s, GBS emerged as the predominant organism causing bacteremia and meningitis in neonates.[13,31,125,164,262] The incidence of neonatal infection remained stable, with reported attack rates ranging from 0.2 to 5.4/1000 live births, until the late 1990s, when maternal intrapartum chemoprophylaxis gained wide acceptance and incidence rates fell.[76,103,302] Invasive infection also occurs beyond the neonatal period in pregnant women, nonpregnant adults with underlying medical conditions, and elderly persons.[102,113,254]

MICROBIOLOGY

Isolation and Identification

GBS are facultative gram-positive diplococci that grow on a variety of bacteriologic media. Colonies are 3 to 4 mm in diameter, grayish white, flat, and somewhat mucoid. Colonies are surrounded by a narrow zone of β-hemolysis that for some strains is detectable only when the colony is lifted from the agar. Nonhemolytic strains account for 3 to 4 percent of isolates and can cause human disease.[13,293] Definitive identification of GBS relies on detection of the group B–specific antigen, a carbohydrate cell wall antigen common to all strains. The standard method, as described by Lancefield,[191] requires acid treatment of the bacteria to solubilize the carbohydrate group B antigen, followed by capillary precipitation with hyperimmune rabbit serum. Several newer methods using hyperimmune antisera have been developed, but latex agglutination is used widely because of the commercial availability of test kits, the ease of performing the assay, and the specificity of the results when organisms in pure culture are tested.[314] Other laboratory methods for presumptive identification include testing for resistance to bacitracin or trimethoprim-sulfamethoxazole, hydrolysis of sodium hippurate broth, failure to hydrolyze bile esculin, production of orange pigment when cultured under certain conditions, and CAMP (Christie, Atkinson, Munch, Peterson) testing. *CAMP* is an acronym of the names of the authors who first described the production of CAMP factor by GBS in the presence of the α-toxin of *Staphylococcus aureus* that results in synergistic hemolysis on sheep blood agar.[83] Chromogenic agars that undergo color change in the presence of β-hemolytic colonies can facilitate detection of β-hemolytic strains but will miss the majority of nonhemolytic strains (~4% of isolates).[326,341] In addition, recently developed rapid techniques for identifying group GBS from enrichment broth include DNA probes and nucleic acid amplification tests, such as polymerase chain reaction (PCR).[341]

Serologic Classification and Antigenic Structure

GBS possess two carbohydrate cell wall antigens—the group B–specific antigen and type-specific capsular polysaccharide. GBS are classified into serotypes based on type-specific capsular polysaccharides. Nine such polysaccharides are characterized: Ia, Ib, and II through VIII. The type-specific polysaccharides of GBS are repeating units of five to seven monosaccharides (glucose, galactose, glucosamine, and *N*-acetylneuraminic acid). All of the characterized polysaccharides include an *N*-acetylneuraminic acid (sialic acid) residue, which is important in the pathogenesis of type III human infection and perhaps other types.[29,309,352] Despite structural relatedness, antibody directed against the capsular polysaccharide of one type does not provide cross-protection against other capsular polysaccharide types.[192,343,354] A few strains isolated from patients with systemic infection contain type-specific capsular polysaccharide genes by genotypic methods but express low levels of capsule or have modified capsular structures that do not react with hyperimmune sera or monoclonal antibodies to the characterized capsular polysaccharides.[282] These strains are termed *nontypeable*.

Further differentiation of type Ia strains was based on the presence or absence of a protein antigen known as C, which led to the nomenclature of Ia and Ia/c serotypes. The C protein also is present in many other serotypes, except type III strains. Two components make up the C protein: α (trypsin resistant), found in 70 percent of non–type III capsular polysaccharide isolates, and β (trypsin

sensitive), found in approximately 20 percent of isolates.[120,172,221] GBS express additional surface proteins, including α-like repetitive proteins (Alp), also referred to as R proteins. R1 and R4 (shown to have an identical gene sequence to Rib) are the major R proteins found on clinical isolates.[122]

Pili, an essential virulence factor in many gram-negative pathogens, was discovered in GBS in 2005[197] and may play a role in attachment and invasion of host cells[218] and resistance to macrophage phagocytosis.[171] Ongoing analyses of the GBS genome sequenced from multiple pathogenic strains will provide further insights into its antigenic structure, genes contributing to its virulence, and targets for treatment and prevention.[134,235,328,329]

Extracellular Products

Several bacterial products are elaborated by GBS. Type-specific capsular polysaccharide is released from cells, and the amount elaborated has been correlated with virulence.[187,363] These soluble polysaccharides inhibit opsonophagocytic killing in vitro, thereby providing a mechanism for the documented increase in virulence.[200] Most strains possess C5a-ase, an enzyme of the serine esterase class that inactivates complement component C5a.[159] Because C5a is a potent chemoattractant for neutrophils, this enzyme helps the bacteria evade the host immune system by hindering the accumulation of neutrophils at the site of infection. The β-hemolysin elaborated by GBS was characterized in 1980; its role in virulence has been explored through the creation of nonhemolytic and hyperhemolytic mutants.[224,348] Expression of β-hemolysin correlated with tissue damage in an in vivo arthritis model[278]; activation of neutrophil signaling pathways in brain endothelium, leading to development of meningitis[97]; induced neuronal damage[287]; increased virulence in pulmonary infection in rats and rabbits[154,251]; and directly impaired cardiomyocyte viability and function.[153] Other bacterial products of GBS, including CAMP factor,[155,180] lipoteichoic acid,[152,248,249] pigment,[211,325] hippuricase,[121] hyaluronidase,[233] and nucleases,[123] have been described, but the contributions of these substances to pathogenesis are not clear.

Antimicrobial Susceptibility

To date, human isolates of GBS have remained uniformly susceptible to penicillin G. However, approximately 10-fold greater concentrations are required for inhibition and killing of GBS than for group A streptococci. GBS also are susceptible to other β-lactam agents, cephalosporins, vancomycin, and carbapenems. The prevalence of resistance to the macrolides (i.e., erythromycin, clindamycin, and clarithromycin) is increasing; from 1970 to 1990, resistance was reported in 3.4 to 7.4 percent of isolates, but more recent studies reported resistance to erythromycin in 17 to 40 percent of isolates and resistance to clindamycin in 7 to 30 percent.[56,91,118,291] Resistance is related to the presence of *ermTR*, *ermB*, or *mefA* genes.[91] Macrolide resistance is highest in type V strains.[205] Furthermore, inducible clindamycin resistance can occur in some strains that appear susceptible in broth susceptibility tests; therefore, D-zone testing is important to identify these strains.[291] Ninety-five percent of strains are resistant to tetracycline, and resistance to bacitracin, nalidixic acid, trimethoprim-sulfamethoxazole, and metronidazole is uniform.[268] Low-level gentamicin resistance is typical, but when gentamicin is combined with either penicillin G or ampicillin, synergistic killing of GBS occurs in vitro and in vivo.[298,299,322]

As many as 5 to 17 percent of GBS isolates have been reported to be tolerant to penicillin.[48,183] Expression of tolerance requires laboratory conditions that promote a greater than 16-fold discrepancy between minimal inhibitory concentrations and minimal bactericidal concentrations. Tolerant strains are characterized in vitro by delayed penicillin killing, similar rates of killing by penicillin whether growth is exponential or stationary, an additive rather than a synergistic response to the combination of penicillin and gentamicin, and deficient autolysis. The clinical significance, if any, of these laboratory-induced properties remains unknown.[184,185,312]

EPIDEMIOLOGY

Maternal Colonization

Asymptomatic colonization occurs at vaginal, rectal, urethral, and pharyngeal sites in up to one third of healthy young women.[53,238] Much effort has been exerted trying to define groups of women at enhanced risk for colonization with GBS. Factors found to be associated with vaginal acquisition include black ethnicity, multiple sex partners, frequent sexual intercourse, male-to-female oral sex, tampon use, and infrequent hand washing.[53,220,238] Women younger than 20 years of age have higher prevalence of colonization.[14,33] Several studies have found significantly higher colonization rates among blacks,[72,158,238] whereas others found higher rates in Hispanics.[285] Asians have the lowest colonization rates.[72,238]

Maternal vaginal or rectal colonization rates during pregnancy vary from 18 to 35 percent in reported studies.* These rates relate to the body sites sampled, microbiologic techniques employed, and the period of gestation in which the cultures are performed. Specimens from the distal portion of the vagina yield GBS more frequently than do specimens from the proximal vagina or cervix.[215] Concomitant sampling of the rectal site results in a 10 percent increase in detection over culturing the vaginal site alone.[21,94] Several investigators have suggested the gastrointestinal tract as the principal reservoir for this organism, and sometimes the rectal site is the only one that yields GBS.[21,94,162,269] The urinary tract is an important site of infection (asymptomatic bacteriuria) because it is a surrogate for a high-density or "heavy" (>10^5 colony-forming units/mL) genital inoculum and a marker of increased risk for development of early-onset sepsis in neonates.[246,359] Bacteriuria mandates therapy during pregnancy.[341]

The manner in which swab specimens from the vagina and rectum are processed also is important in accurately

*References 21, 24, 60, 94, 101, 232, 269, 285.

assessing colonization.[74,341] Anogenital culture swabs collected by patients themselves are as accurate as those performed by physicians.[17,277,331] Swabs can be placed in transport media at environmental temperatures for as long as 96 hours.[341] Specimens then should be placed in a selective antibiotic-containing enrichment broth medium, rather than on solid media, because solid media fail to detect as many as 50 percent of GBS carriers.[27,32] The addition of antibiotics to the broth limits the growth of competing flora, especially gram-negative enteric organisms, and enhances detection.[24,27,32,229] Todd-Hewitt broth with gentamicin and nalidixic acid (selective broth medium)[27] or with colistin and nalidixic acid (Lim broth)[204] is recommended for detection of GSB colonization.[341] After overnight incubation, the broth is subcultured onto a 5 percent sheep blood agar plate and is processed conventionally.

Of culture-positive women, 92 percent are identified if lower vaginal and rectal cultures are obtained at a single visit with correct laboratory detection methods.[100] The proximity to delivery affects the accuracy of predicting colonization at delivery. Cultures obtained at 35 and 37 weeks of gestation predict colonization at delivery with 87 percent sensitivity and 96 percent specificity.[60,269,362]

Infant Colonization

Colonization and infection in the neonate are associated significantly with the presence of GBS in the maternal genital tract at delivery. Vertical transmission from colonized mothers to their infants occurs in 41 to 72 percent of cases (mean, ~50%).* Only 1 to 12 percent (mean, ~5%) of colonized infants are born to noncolonized mothers.[15,24,99,232,365] Acquisition is presumed to occur either by the ascending route through ruptured membranes or from contact with the organism in the genital tract during parturition. Heavy maternal inocula in the genital tract ($>10^5$ colony-forming units/mL) greatly increase the rates of vertical transmission to neonates and rates of heavy infant colonization.[10,15,58,162,174] Other factors associated with increased colonization rates in infants include prolonged rupture of membranes (>12 to 18 hours) and vaginal delivery.[15,158] Maternal intrapartum antibiotic therapy substantially diminishes the vertical transmission of GBS.† The body sites in neonates most likely to yield GBS are the rectum and throat, findings reflecting replication of organisms at the respiratory or gastrointestinal tract sites after the ingestion of infected amniotic fluid or genital secretions.[158]

Horizontal transmission from nosocomial and community sources has been described.[1,100,129,253] Infant-to-infant or colonized staff member–to-infant spread may occur through hands of hospital personnel, but epidemics are rare.[100,253] The rate of community acquisition, presumably by an oral–fecal route, appears to be low, but this has not been investigated thoroughly.[129,222] Breast milk also has been proposed as a mode of transmission for late-onset infection; most reported cases involved a mother with postpartum mastitis.[50,189,288]

*References 7, 15, 24, 58, 100, 158, 232, 366.
†References 7, 58, 60, 158, 340, 366.

Incidence of Disease

Before the widespread use of maternal intrapartum chemoprophylaxis to prevent early-onset disease, reported attack rates for GBS disease in infants ranged from 1.8 to 4.0/1000 live births.[254,349,368] Early-onset disease (onset within the first 6 days of life) accounted for approximately 80 percent of cases.[302] Late-onset disease (onset from 7 through 89 days of life) rates ranged from 0.3 to 1.8/1000 live births.[95,262] With the 2002 guidelines for universal screening of pregnant women at 35 to 37 weeks of gestation and administration of intrapartum chemoprophylaxis to carriers, the incidence of early-onset disease decreased and stabilized at approximately 0.3 cases/1000 live births since 2004, a finding representing a decline of 81 percent from 1990.[302,341] However, the incidence of late-onset disease has remained unchanged.[175,341] Approximately 30 percent of cases of early-onset disease and up to 55 percent of those of late-onset and late, late-onset disease now occur in preterm infants.[207,301,305] Late, late-onset GBS disease occurs in infants older than 3 months of age and accounts for 7 to 13 percent of childhood GBS infections.[165,302,361] Affected infants typically were born before 34 weeks of gestation or have an underlying immunodeficiency or concomitant infection with human immunodeficiency virus (HIV).[92,165,361] Case-fatality rates for all infants with GBS disease have dropped from 46 percent in the 1970s to 4 to 6.5 percent in recent years.[170,271,341]

GBS disease also is a common finding in pregnant women, with clinical manifestations that include urinary tract infection (usually asymptomatic bacteriuria but also cystitis or pyelonephritis), intra-amniotic infection, postpartum endometritis (often with bacteremia), and puerperal sepsis.[261,306,367] Occasionally, meningitis, septic thrombophlebitis, and other serious complications occur.[367] Attack rates of 2/1000 deliveries have been reported, and 28 percent of maternal cases are associated with pregnancy loss or birth of an infant with early-onset GBS disease.[261,367] Nonpregnant women and men account for 68 percent of invasive GBS disease in adults.[113] These patients typically are older than 65 years of age or have underlying medical conditions, especially diabetes mellitus, but also malignancy (e.g., breast cancer or leukemia), HIV infection, liver disease, stroke and other neurologic disorders, decubitus ulcers, and neurogenic bladder.[102,113,168,254,335]

Risk Factors for Infant Disease

Vertical transmission is a prerequisite for the development of invasive, early-onset infection.[24,231,262] Evidence suggests that approximately 50 percent of late-onset infections also occur after vertical transmission or from spread within the household.[95] The degree of colonization or inoculum also increases the likelihood of infant disease; heavily colonized mothers are more likely to have infants with invasive infection, and heavily colonized infants are more likely to have either early- or late-onset disease.[61,95,174,203] Other maternal factors associated with the development of early-onset disease include delivery before 37 weeks of gestation, premature rupture of

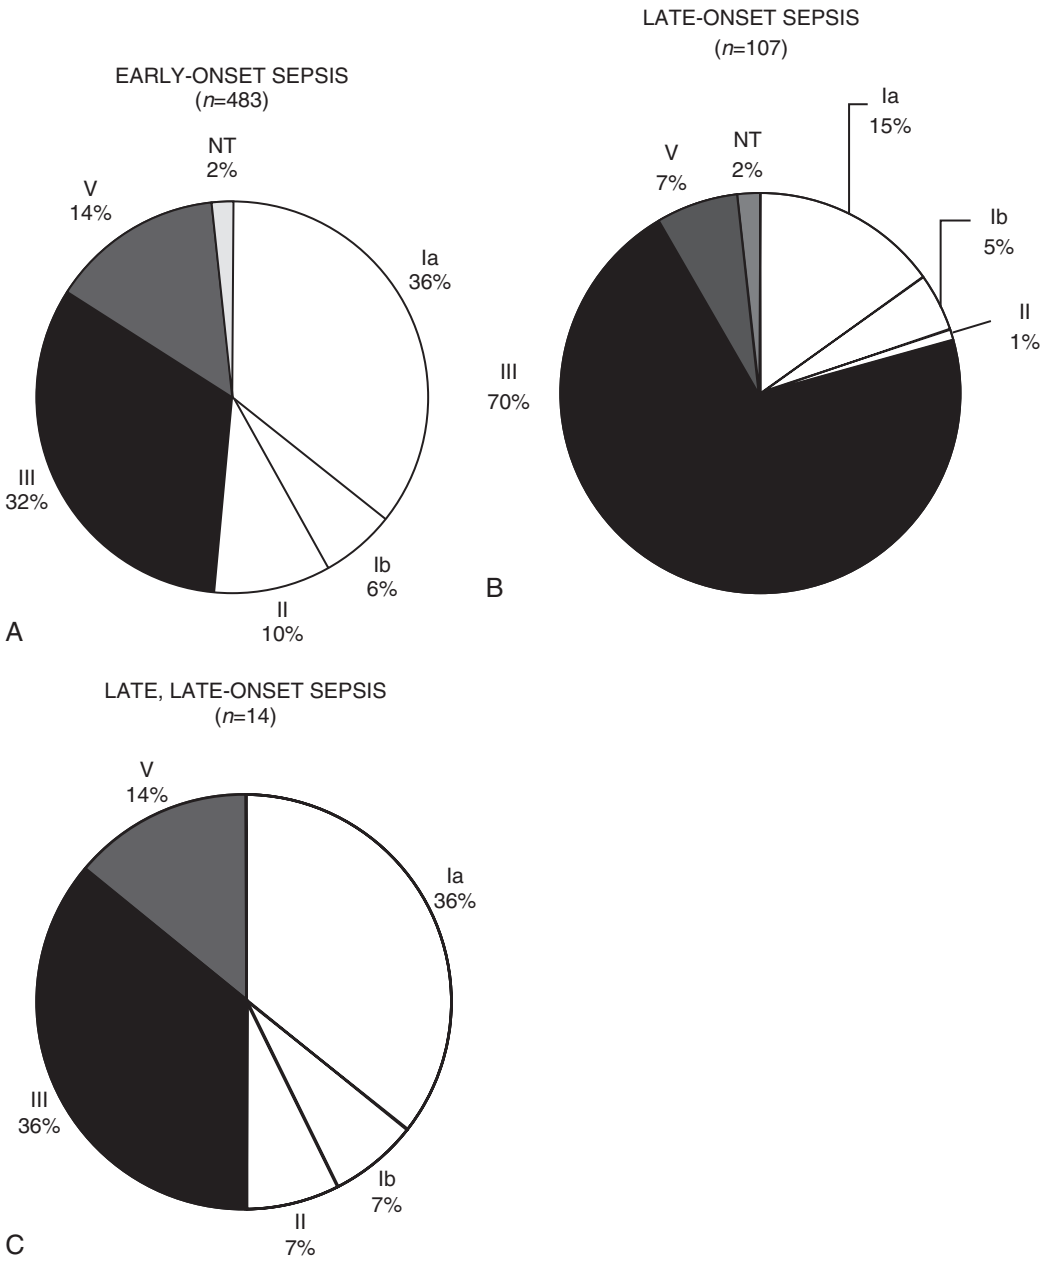

FIGURE 83-1 ■ Serotype distribution of invasive group B streptococcal strains causing early-onset, late-onset **(B),** and late, late-onset **(C)** disease in infants.[54,87,144,205,367] *NT,* Nontypeable.

membranes (i.e., rupture of membranes before onset of labor) or rupture of membranes more than 18 hours before delivery at any gestation, and intrapartum fever.* Women colonized with GBS also have a higher incidence of premature rupture of membranes and preterm labor, a finding suggesting a possible causal relationship between GBS and events leading to preterm birth.[6,230,234,285] Other maternal factors associated with an increased attack rate of early-onset infection are black ethnicity, age younger than 20 years, history of previous fetal loss, history of urinary tract infection with GBS during the current pregnancy, and primiparity.[305,306] Late-onset disease also is associated with young maternal age and black ethnicity.[306]

*References 13, 59, 60, 95, 125, 149, 262.

Siblings of infected infants who are the product of a multiple pregnancy (e.g., twins, triplets) have enhanced risk for development of early- and late-onset GBS disease.[106,260]

Capsular Polysaccharide Types Causing Disease

Reports from the 1970s indicated that the GBS capsular polysaccharide types colonizing pregnant women and neonates were divided fairly evenly among types I, II, and III.[28,354,355] The current distribution of capsule polysaccharide types in invasive disease from multiple North American studies is shown in Figure 83-1.[87,144,206,350,367] Serotypes Ia and III are the most common cause of

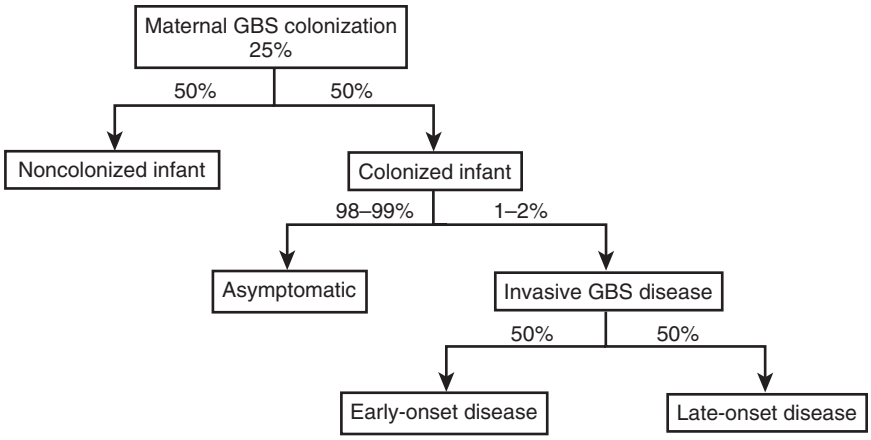

FIGURE 83-2 ■ Flow chart of vertical transmission and disease manifestation of group B streptococcal disease in the era of intrapartum chemoprophylaxis.

early-onset infection, whereas serotype III is the most common cause of late-onset infection. In Europe, type III predominates in both early- and late-onset disease.[124,332,350] Serotype III is implicated in 80 to 93 percent of meningitis cases, either as a focus of early-onset disease or as a manifestation of late-onset infection (80 to 93%).[25,31,355] Capsular polysaccharide type V emerged in the 1990s.[54,72,158,288] Type V causes both early- and late-onset infant disease and is the type most commonly isolated from adults with invasive disease.[54,289] In Japan, types VI and VIII are the most common isolates from pregnant women.[190] Recent studies from the Middle East and Africa suggest type IV may be an emerging pathogen.[93] The least common serotypes causing human disease are types Ib/c, VI, VII, and VIII.

PATHOGENESIS

For pediatricians, GBS disease predominantly afflicts neonates, a predilection that results from a unique combination of maternal, bacterial, and host factors. Figure 83-2 shows a simplified flow chart of GBS transmission. First, an organism carried by an asymptomatically colonized mother is transmitted vertically to her neonate. Evidence suggests that this transmission may occur in utero shortly before birth or during parturition. This continuum in time of acquisition is reflected in the time of onset of symptoms; infected neonates often are ill at or within 12 hours of birth (up to 90% of cases), whereas others may not have evidence of disease for a few days.[31,306] The organism successfully colonizes approximately 50 percent of all infants born to GBS carriers, yet disease develops in only 1 to 2 percent of these infants.[13,304] A breach in the delicate interplay of maternal, infant, and bacterial factors allows the organism to invade. Once invasion occurs, a combination of host defenses and therapeutic interventions may halt the progression of disease or the infant's defenses may fail and the disease may progress and result in tissue damage or death.

Maternal Factors

The bacterial inoculum in the maternal genital tract determines the likelihood that the organism will be transmitted vertically. Infants born to heavily colonized women are more likely to be colonized themselves and are more likely to have early-onset disease.* Infants delivered before 37 weeks of gestation have an increased risk for development of early-onset disease. Heavy maternal colonization may induce preterm delivery,[115,231,234,284,286] and disease is more likely to develop in the infant in this setting of high bacterial inoculum and immunologic immaturity. Invasive disease also has been reported in term neonates delivered by elective cesarean section with intact membranes, but this is a rare event.[13,90,109,181,261]

In addition to bacterial inoculum, another critical maternal factor is the concentration of serum antibody to the serotype-specific polysaccharide capsule of the colonizing strain of GBS at delivery. Antibody to the type-specific capsular polysaccharide is protective against the homologous serotype in the mouse model of lethal infection; antibody to the group B polysaccharide is not.[194] Baker and associates[28,34] determined that invasive disease with type III GBS occurred primarily in infants born to women with low serum concentrations of antibodies directed against the type III capsular polysaccharide. Several other investigators also reported a correlation between low concentrations of antibody to types Ia, Ib, II, and III capsular polysaccharide in maternal delivery sera and the occurrence of early- and late-onset GBS infant disease.[136,138] A correlation between antibody concentration and maternal age may explain the epidemiologic association of young maternal age and increased likelihood of neonatal disease.[13] Animal models have demonstrated that antibody directed against the α or β determinants of C protein is protective,[194,239] but definitive human studies are lacking. Invasive disease, but not colonization, elicits immunoglobulin (Ig)M and IgG antibodies to α and β C protein in humans.[255,256] Antibody to other protein determinants in some serotypes has been postulated to be partially protective. Titers of antibody to R protein were found to be higher in maternal serum from mothers colonized with R protein–bearing strains whose infants were healthy than from mothers whose infants were ill; such antibodies were protective in a mouse model against type II, but not type III strains.[208,209] Presence of maternal antibody to Rib also was associated

*References 10, 15, 60, 95, 162, 174.

with protection in neonates against Rib-expressing GBS strains.[196]

Bacterial Factors

To colonize the genital tract or cause disease effectively, organisms must be able to adhere to host tissue. GBS adhere well to many types of epithelium, including vaginal epithelium and chorioamniotic membranes.[128,225,315,324] Type III strains adhere more avidly to vaginal cells than do other serotypes in vitro.[57] Furthermore, invasive strains adhere better to epithelial tissue than do colonizing strains.[150] This capacity to adhere to and possibly invade chorioamniotic cells may explain the association of GBS colonization with preterm labor and premature rupture of membranes. If a breach occurs in the membranes, the bacteria can multiply in amniotic fluid.[151] After transmission and colonization occur, the capacity of the bacteria to adhere to neonatal epithelial cells may allow them to invade and disseminate. The lung, after aspiration of infected maternal fluids, is a frequent initial site of infection in a newborn with early-onset disease. GBS can adhere to and invade respiratory epithelial cell lines.[295] In addition, they can invade endothelial cells, which may be a mechanism for some of the pathologic features of disseminated disease.[132]

Several factors may confer adherence properties of GBS, including bacterial cell wall component lipoteichoic acid[249] or surface proteins.[68,324] Studies suggest that translocation across epithelial barriers is mediated by alpha C protein binding to host cell surface glycosaminoglycan.[42,78] Several proteins with potential roles in adherence and invasion were identified by detecting upregulation during cell invasion using proteomics and include an undefined surface antigen, penicillin-binding protein 2b, glyceraldehydes-3-phosphate dehydrogenase, and an iron-binding protein.[173] Mouse antisera to these five proteins inhibited binding of GBS to cervical epithelial cells. Translocation also may occur by a paracellular route.[270,318] Adherence to and invasion of the microvascular endothelial cells of the blood-brain barrier has been associated with proper anchoring of lipoteichoic acid,[98] β-hemolysin/cytolysin,[97] fibrinogen binding protein FbsA,[327] and pilus proteins.[218]

A well-defined virulence structure of GBS is the capsular polysaccharide. Mouse virulent strains are able to synthesize greater amounts of surface-bound type-specific polysaccharide than avirulent strains.[187,363] An unencapsulated mutant, created by inserting a transposon into the gene regulating capsule expression, has significantly less virulence in neonatal rats than does the parent type III strain.[296] As with other encapsulated organisms, the capsule is thought to confer virulence primarily by interfering with opsonophagocytosis.[200] In vitro, the capsule of type III GBS has been shown to prevent the deposition of C3,[227] and the presence of the terminal sialic acid residue on the repeating unit of this polysaccharide is crucial to this interference.[103] Removal of sialic acid residues from the polysaccharide leads to diminished virulence, and a desialylated mutant loses virulence in contrast to the parent strain.[353] Furthermore, the presence of this sialic acid moiety prevents activation of the alternative complement pathway, the predominant pathway used by the human host when minimal type-specific antibody is present.[103] In addition, when bacteria grow in the presence of human serum, the quantity of sialic acid increases, thereby potentiating its contribution to virulence.[273] Opsonization may be affected by cell surface components other than capsular sialic acid. C protein also lends relative resistance to opsonization to strains bearing the antigen.[172,264] β-Hemolysin/cytolysin contributes to cytolysis and apoptosis of phagocytes while protecting GBS by the linked carotenoid pigment against oxidative damage.[211]

Sialic acid residues on the capsule may interfere with another component of the immune system. In a serum-free system, the desialylated mutant of type III GBS elicited much larger quantities of leukotriene B_4 from macrophages than did the parent strain.[294] Leukotriene B_4 is a potent neutrophil chemoattractant, so this effect may result in diminished influx of effector cells. Similarly, C5a-ase may disable C5a, another host product capable of eliciting neutrophil influx. By enhancing phagocytosis and killing GBS, C5a also has direct stimulatory effects on neutrophils.[323] Bacterial elaboration of C5a-ase may affect both the accumulation of neutrophils and the efficiency of neutrophil function.

Once invasive infection is established, ongoing replication and digestion of bacteria can instigate host inflammatory responses that may be deleterious. Neonates recovering from GBS disease have circulating immune complexes for a prolonged period, and immune complexes can contribute to end-organ damage.[336] Additionally, immune complexes containing GBS components elicit inflammatory mediators such as leukotriene B_4 and interleukin (IL)-6. The cytokine response to gram-positive pathogens is not delineated as clearly as is that to gram-negative bacteria, partly because of the greater heterogeneity in structure of the latter.[55] Both group B and type III capsular polysaccharides induce the release of IL-6 from monocytes[318]; group B antigen also causes the release of tumor necrosis factor-α (TNF-α).[338] As with other gram-positive pathogens, the cell walls of GBS contain peptidoglycan and lipoteichoic acid. Peptidoglycans from other gram-positive organisms elicit a variety of proinflammatory cytokines such as TNF-α, IL-1, IL-6, and granulocyte colony-stimulating factor.[96,157,292] Lipoteichoic acid also induces the release of IL-1β, IL-6, and TNF-α.[49,182] GBS cell wall components likewise exert similar effects. Elaboration of these cytokines has been implicated in the clinical and hemodynamic effects of sepsis.[55,351] Specifically, blockade of IL-1 activity by administration of an IL-1 receptor antagonist in a piglet model of GBS sepsis ameliorated systemic hypotension and prolonged survival.[339]

Infant Host Factors

Neonates have several domains of immune dysfunction that affect their ability to mount a sufficient defense against GBS. Neutrophils are the primary effector cell in host defense against extracellular bacterial pathogens, and neutrophils from neonates have many functional abnormalities.[201] The generation of chemotactic activity

TABLE 83-1 **Features of Group B Streptococcal Disease in Infants**

Feature (References)	Early-Onset Disease	Late-Onset Disease	Late, Late-Onset Disease
Age at onset[59,65,306]	≤6 days; mean, 8 hr; median, 1 hr	7-89 days; mean, 36 days; median, 27 days	≥90 days
Infants affected[75,142,306,349]	Premature neonates, births after maternal obstetric complications	Term and preterm infants equal	Premature neonates <32 wk gestation, immunodeficiency
Clinical findings[103,199]	Acute respiratory distress, apnea, and hypotension common	Fever, irritability, nonspecific signs, occasionally fulminant	Fever, irritability, nonspecific signs
Manifestations[13,23,104,125,175,349,361]	Bacteremia (40%-55%), pneumonia (30%-45%), meningitis (6%-15%)	Bacteremia without a focus (55%-67%), meningitis (26%-35%), osteoarthritis (~5%), cellulitis/adenitis (~2%)	Bacteremia without a focus, focal infections as in late-onset disease
Case-fatality rate[76,175,302,306,349,361]	5%-15%	2%-6%	<5%

in neonatal serum in response to GBS is diminished, as is the release of chemotactic factors by neonatal monocytes.[11,12,20] Thus, the diminished ability of neutrophils to migrate is amplified by a diminished level of chemotactic stimulation. Phagocytosis and bacterial killing also are impaired when opsonic activity is poor, as is the usual pattern in neonates with sepsis.[201] The neutrophil storage pools of neonates rapidly become depleted during invasive infection, thereby leading to profound neutropenia,[82] an ominous prognostic indicator.[265] These defects in neonatal neutrophils are even more pronounced in infants born prematurely.[201]

Cells of the monocyte/macrophage lineage also may play a role in host defense against GBS streptococci, especially in the lungs, where the alveolar macrophage is the first effector cell to encounter pathogens. Defects in the functions of these cells have been described in neonates, especially preterm infants.[86] Cord blood monocytes have impaired phagocytosis and killing of GBS.[226] In animal models, oxidative metabolism, bacterial uptake, and migration to the site of infection by neonatal macrophages are diminished in response to GBS.[228,307,308]

Humoral immunity is compromised in neonates. Both the alternative and classical complement pathways are affected, and preterm neonates are impaired more severely than are term neonates.[89,105] Both pathways are important in the opsonization of GBS.[108] The concentration of type-specific antibody passively acquired from the mother is an important protective factor. Because passive transfer of IgG increases dramatically during the final 8 weeks of pregnancy, premature neonates are again at a disadvantage because they may not receive sufficient amounts of type-specific IgG if they are born before protective levels are transferred.[81]

The pattern of production of cytokines by neonatal immune cells frequently is altered in contrast to that of adults. For example, in response to GBS, the level of TNF-α and IL-6 released by neonatal monocytes is increased relative to adults,[337,338] but levels of IL-8 and leukotriene B_4 are decreased.[294,300] IL-12 and interferon-γ are associated with improved outcome in an animal model of GBS infection, but lower quantities of these mediators are released by neonatal mononuclear cells.[179,219] Impairment in the innate recognition systems, including Toll-like receptors (TLRs) and nucleotide-binding oligomerization domain (NOD)-like receptors may lead to reduced cytokine production and pathogen clearance.[85,297] Monocytes from newborns show lower TLR-mediated cytokine production compared to adults.[86,297] Cytokine networks are important both in the manifestations of sepsis and in the stimulation of an appropriate immune response, so alterations in expression of cytokines may affect the neonate's response to this pathogen both clinically and immunologically.

CLINICAL MANIFESTATIONS

Early-Onset Disease

GBS remains the leading cause of neonatal sepsis since the 1970s and accounts for 40 to 50 percent of early-onset sepsis cases.[40,52,103,166] The bimodal distribution of GBS infections corresponding to age of neonates and young infants was described first in 1973 and now is divided into two types, termed *early-* and *late-onset disease*.[31,125] The syndromes of early- and late-onset disease differ in epidemiologic characteristics, pathogenesis, clinical findings, and prognosis. Their major clinical features are detailed in Table 83-1. Early-onset disease is defined as onset of infection in the first 6 days of life, but most neonates (61% to 95%) become ill within the first 24 hours (median, 1 hour).[59,65,149,306] Premature infants often are ill at birth or within 6 hours of birth and account for 17 to 32 percent of neonates with early-onset GBS disease.[22,279,302,306] In infants with very low birth-weight, GBS has dropped to the second most common cause of early-onset sepsis, after *Escherichia coli*, since the implementation of intrapartum antibiotic chemoprophylaxis.[320]

Early-onset disease often occurs in the setting of maternal complications, including labor before 37 weeks of gestation, prolonged rupture of membranes for more than 12 to 18 hours, intrapartum fever greater than 38° C (100.4° F), chorioamnionitis, and early postpartum febrile morbidity.* In one study, neonates born to a mother with one or more of these risk factors were 12.5 times more

*References 45, 59, 60, 95, 149, 349.

likely to develop early-onset GBS in contrast to those born to a mother with no risk factors.[59] Term infants can develop GBS disease without definable maternal risk factors, except vaginal or rectal colonization.[103] In other studies, 65 to 76 percent of mothers of neonates with early-onset disease had deliveries complicated by at least one of the previously mentioned identifiable risk factors or was known to be a GBS carrier.[149,279]

The three most frequent clinical manifestations are bacteremia without a focus, pneumonia, and meningitis.[13,349,361] The presentation for each may range from shock and respiratory failure at delivery to a healthy infant who has infection detected during evaluation because of maternal risk factors known to increase the risk for development of invasive infection.[279,349] Respiratory distress, including apnea, grunting respirations, tachypnea, and cyanosis, is the most common initial manifestation in all forms of early-onset GBS disease.[22,31,125,342,361] Other signs include lethargy, poor feeding, abdominal distention, pallor, jaundice, tachycardia, and hypotension. Fever usually is present in term neonates, but preterm infants often are normothermic or hypothermic.[349] Administration of intrapartum antibiotic prophylaxis to the mother does not alter the findings in infants in whom early-onset disease develops despite administration of intrapartum chemoprophylaxis; most still become clinically ill in the first 24 hours of life.[40,65]

Bacteremia without a focus is present in 27 to 87 percent of neonates with early-onset disease.[305,349,361] Signs of septicemia, such as respiratory distress and poor perfusion, often are present, especially in neonates born at less than 37 weeks of gestation.[349] Bacteremia in healthy-appearing term infants also may develop, and in one series it occurred in 22 percent of cases.[164,349,361] These infants probably remained healthy because of early evaluation and institution of empirical antimicrobial therapy.[349] Most often, bacteremic infants are mildly ill and have fever and nonspecific signs that should prompt bacteriologic evaluation. Bacteremia also frequently accompanies pneumonia and meningitis.

Radiographic findings of pulmonary involvement include infiltrates suggestive of congenital pneumonia, small pleural effusions, a pattern similar to that of hyaline membrane disease or respiratory distress syndrome, and increased vascular markings as seen in transient tachypnea of the newborn; radiographs may appear normal despite abnormal pulmonary signs.[202,212,342] In preterm neonates, the findings frequently are identical to those of respiratory distress syndrome; at autopsy, hyaline membranes containing bacteria and minimal inflammatory infiltrates have been described.[2,342]

Meningitis is documented in 6 to 15 percent of neonates with early-onset disease (Figure 83-3).[304,349,357] As a rule, no meningeal signs are present, thus underscoring the need to evaluate all neonates with presumed early-onset disease for the possibility of meningeal involvement.[349,357] Early in the course, the cerebrospinal fluid (CSF) white blood cell count may be normal despite isolation of GBS.[13] Again, respiratory distress is the most frequent clinical finding.[31,199,349] Seizures rarely are the initial feature but do occur in as many as 50 percent of affected neonates early in the course of therapy; often these seizures are focal and subtle.[31] Postmortem evaluation of infants who die of early-onset GBS meningitis reveals hemorrhage, prominent basilar involvement, and abundant bacteria with relatively sparse inflammation.[125]

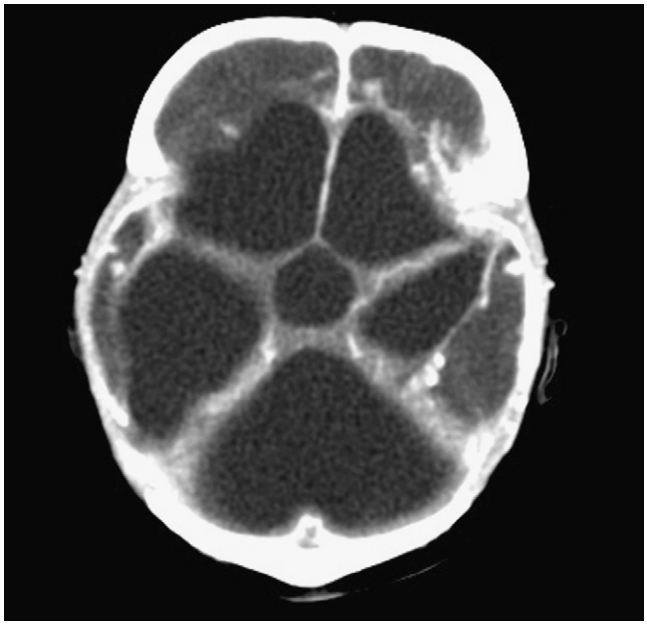

FIGURE 83-3 ■ Head computed tomography scan at 6 weeks of age from a term infant with early-onset group B streptococcal meningitis shows significant loss of normal brain matter.

Late-Onset Disease

Late-onset disease is defined as infection in infants 7 to 90 days of age, and it primarily affects term infants with an unremarkable maternal history and early neonatal course.[31,95,175] However, a recent case series suggested that late-onset infection develops in a larger proportion of infants born quite prematurely (<34 weeks of gestation).[207] Bacteremia without a focus and meningitis are the two most common manifestations of late-onset disease.[125,267,361] Osteoarticular infections and cellulitis are additional clinical foci.[23,104,361] Whereas early-onset disease most frequently occurs acutely with apnea and hypotension, late-onset disease often is manifested by fever, irritability, and other nonspecific signs.[103] More fulminant, rapidly progressive cases do occur, however.[31]

Meningitis is a frequent complication, occurring in 26 to 40 percent of late-onset disease cases.[31,175,349,361] GBS accounted for 86 percent of infants younger than 2 months of age with meningitis in a recent multistate epidemiologic study.[330] Late-onset meningitis most typically manifests with fever and lethargy, although respiratory distress, coma, and shock also may occur.[31] Classic signs of meningitis, such as a bulging fontanelle and nuchal rigidity, occur more commonly in neonates with late-onset than early-onset meningitis. Subdural effusions develop in as many as 20 percent of cases, but subdural empyema is a rare occurrence.[14,31,260] Infants

who die of late-onset meningitis have purulent leptomeningitis at postmortem examination.[125]

Sequelae occur in 20 to 30 percent of survivors of early- and late-onset meningitis. These sequelae include developmental delay and cognitive impairment, spastic quadriplegia, cortical blindness, deafness, uncontrolled seizures, hydrocephalus, and speech and language delay.[103,199,344] Signs at admission correlated with a high likelihood of a poor outcome include seizures, coma or semicoma, hypotension requiring initial pressor support, neutropenia, CSF protein levels greater than 300 mg/dL, CSF glucose lower than 20 mg/dL, and high concentrations of bacterial capsular polysaccharide antigen in CSF.[39,108,199,264]

Late, Late-Onset Disease

Contemporary studies show an increasing incidence of GBS infection in infants older than 3 months of age, defined as late, late-onset disease.[165,199,302,361] These infections tend to occur in infants who were born extremely prematurely and whose corrected postmenstrual age is less than 3 months.[165,302,361] Late, late-onset disease also occurs in children coinfected with HIV and those with immunodeficiencies,[92,165,361] a finding supporting the recommendation that immunodeficiency be considered in any child infected beyond the usual period of risk.[92] The clinical manifestations in these older infants are similar to those in patients with typical late-onset infection; bacteremia without a focus and meningitis are the most common clinical features.[92,165] Endocarditis and central venous catheter infection also have been noted.[165]

Septic Arthritis and Osteomyelitis

Osteoarthritis occurs in approximately 5 percent of infants with late-onset infection but appears to be diminishing since implementation of maternal intrapartum prophylaxis.[361] Among neonates and young infants with osteomyelitis, GBS have been identified as the causal agent in 7 to 38 percent of cases.[104,358] The osteoarticular disease usually is more indolent than the osteomyelitis caused by other etiologic agents in young infants. Diagnosis usually is established after a mean of 9 days of clinical signs at a mean age of 31 days.[103,104] Decreased motion of the involved extremity and pain with manipulation are common signs. Warmth and redness are uncommon findings but have been described.[104] Systemic signs and symptoms, including fever, are unusual manifestations.[104,234]

GBS has a predilection for the proximal humerus.[104] The femur is the second most commonly affected bone. Involvement of more than one bone is an unusual finding.[104] However, involvement of the adjacent joint is described.[236] Blood cultures infrequently are positive, unlike neonatal osteomyelitis caused by other etiologic agents. A lytic lesion often is seen on radiographs at first evaluation (Figure 83-4). This observation suggests that lytic lesions may be a late phenomenon that develops after seeding of the metaphysis during an episode of asymptomatic, early-onset bacteremia several weeks before presentation.[103]

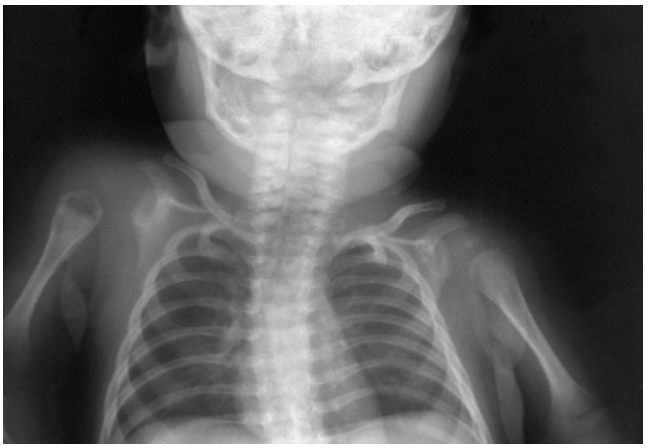

FIGURE 83-4 ■ Radiograph of the right arm of a 26-day-old infant with a 2-day history of diminished movement of that extremity. A well-defined, lytic lesion is present in the proximal end of the humerus. Necrotic material from this area was débrided surgically and grew group B streptococci on culture. (Courtesy Morven S. Edwards, MD.)

The mean age at diagnosis in infants who have septic arthritis without osteomyelitis is 20 days. The clinical picture typically is acute, with a mean of 2 days of abnormal findings before diagnosis is established. The lower extremities are involved most often, with the hip joint predominating. Infants typically present with local joint signs in the absence of systemic symptoms.[236]

Cellulitis and Adenitis

In one case series, 2 percent of late-onset GBS infections were associated with cellulitis and adenitis syndrome.[361] Diagnosis is made at a mean age of 5 weeks, with a preponderance of cases in male patients.[23] Typical presentation includes fever, irritability, poor feeding, and swelling of the affected soft tissue area. Enlarged adjacent lymph nodes become palpable within a few days. The most frequent sites of cellulitis are the face and neck,[23,146,263] with enlarged lymph nodes in the submandibular area. Ipsilateral otitis media was noted in four of five infants with facial or submandibular cellulitis in one case series.[23] Less commonly affected areas reported include the genital or inguinal region (Figure 83-5), the hand, and the prepatellar bursa.[23,62,356] Aspiration of the affected area of cellulitis often yields GBS, and concomitant bacteremia almost always is present.

Other Manifestations

Nearly every organ has been reported to be a site of GBS infection in young infants. Table 83-2 lists these reported unusual manifestations of early- and late-onset disease.

Recurrent Infections

Second (and rarely third) episodes of GBS infection occur in approximately 1 to 2 percent of cases after early- and late-onset infection.[139] In a case series from Houston, the mean age at recurrence was 44 days, and the mean

FIGURE 83-5 ■ This 3-month-old female infant who was born after 28 weeks of gestation had fever, lethargy, swelling of the external genitalia, and erythema that extended to the lower part of the abdomen and the thigh. Blood culture grew type Ib/c group B streptococci. (Courtesy Morven S. Edwards, MD.)

duration between the first course of therapy and recurrence was 19 days.[139] Molecular epidemiologic techniques have indicated that most, but not all, of these recurrent infections are caused by the strain implicated in the first episode; this finding suggests that persistent mucosal colonization after treatment of the first episode is followed by invasion of the bloodstream.[247] Contaminated breast milk also has been implicated as a source of recurrent infection.[189] No specific risk factors are evident in these infants, but most of them are born prematurely.[139]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Laboratory Studies

The diagnosis of GBS infection is confirmed by isolation of this pathogen from a normally sterile body site, including blood, CSF, pleural fluid, bone aspirate, joint fluid, or soft tissue. Cultures of the skin, umbilicus, or mucous membranes do not have clinical significance. Tracheal aspirate cultures that grow GBS indicate neonatal colonization but do not prove pulmonary invasion (pneumonia). Rather, isolation of the organism from blood (or in rare circumstances, lung tissue or the pleural space) is required.

Meningitis in early-onset disease is clinically indistinguishable from bacteremia without a focus, and 10 to 38 percent of neonates with meningitis have negative blood culture results,[357] so lumbar puncture is necessary to determine the presence or absence of meningeal involvement. Lumbar punctures also are indicated in patients with a focal site of GBS infection because each results from bacteremia. For example, GBS grew from CSF cultures in 24 percent of infants with cellulitis or adenitis who underwent lumbar puncture.[5] One study found that if selected criteria were used instead of routine lumbar punctures, the diagnosis of bacterial meningitis would have been missed or delayed in 17 percent of infants.[357]

CSF has had detectable group B antigen in 72 to 89 percent of neonates with meningitis; serum is much less likely to be positive. The only specimens recommended for antigen testing are blood and CSF; urine specimens should not be tested because they are unreliable. Antigen testing should not be used as a substitute for bacterial culture. Proper use of antigen testing should be limited to the setting of symptomatic infants in whom rapid diagnosis may alter therapy or allow proper tailoring of antibiotic choice; for example, a sick neonate with CSF pleocytosis and previous antibiotic administration. These tests are never useful in infants who appear healthy.

A limited study of real-time PCR to detect DNA in the blood of eight neonates with culture-proven GBS sepsis showed positive corresponding results.[177] However, larger, prospective studies are required to evaluate sensitivity and specificity.

The white blood cell count of a neonate with proven GBS sepsis may reflect leukopenia, neutropenia, or leukocytosis.[223,264,342] Manroe and associates[223] found the ratio of absolute immature neutrophils to absolute total neutrophils (I:T index) to be the most reliable index for distinguishing respiratory distress caused by GBS infection from that with a noninfectious origin. Most infected neonates had an elevation greater than 0.20 (91% vs. 4% of uninfected infants). Other markers of inflammation, such as C-reactive protein, may rise with acute infection and decrease in response to therapy.[272,276]

Differential Diagnosis

The signs and symptoms of early-onset GBS disease are clinically indistinguishable from neonatal sepsis caused by other bacterial pathogens such as *E. coli* and other enteric organisms. The timing is somewhat different, with GBS disease appearing in the first day and *E. coli* with onset on the second or third day of life.[170] The prominence of respiratory signs in early-onset disease may lead to confusion with noninfectious causes of respiratory distress such as transient tachypnea of the newborn, persistent fetal circulation, and respiratory distress syndrome.[2,22,264,342] Clinical features that suggest GBS infection include a history of prolonged rupture of membranes, apnea, shock in the first 24 hours of life, a 1-minute Apgar score of 5 or less, and rapid progression of pulmonary disease.[2,22,342]

Modified from Edwards MS, Nizet V. Group B streptococcal infections. In: Remington JS, Klein JO, Wilson CB, et al, editors. *Infectious diseases of the fetus and newborn infant.* 7th ed. Philadelphia: Saunders, 2011, pp. 419-469.

The differential diagnosis of late-onset disease depends on the focus of infection. Meningitis in infants of this age also is caused rarely by *Streptococcus pneumoniae*, *Neisseria meningitidis*, *Listeria monocytogenes*, *Haemophilus influenzae* (type b and nontypeable), and, more commonly, viruses.[330] The findings of osteomyelitis may be subtle; refusal to move the arm may be ascribed to neuromuscular disease or Erb palsy.[104] Careful physical examination usually reveals tenderness over the involved area, and radiographs generally show a lytic defect in the metaphyses.[104] If the organism is isolated from a bone aspirate, the diagnosis is definitive. Finally, as seen in Table 83-2, many unusual manifestations of GBS infection have been described, so this organism should be included in the differential diagnosis of any focal infection occurring in the age group at risk.

TREATMENT

Empirical Treatment

The antimicrobial regimens recommended for the treatment of GBS infection in infants are summarized in Table 83-3. Penicillin G remains the drug of choice because susceptibility is uniform. In the usual circumstance, however, antimicrobial therapy for GBS infection is initiated before culture results are known. Initial empirical therapy for early-onset disease would include ampicillin and gentamicin for the treatment of neonatal pathogens in addition to GBS. Regardless of gestational age, neonates with suspected meningitis and those whose clinical condition will not permit lumbar puncture should receive high doses of ampicillin (300 mg/kg/day) plus gentamicin.[13] This combination is more effective than is either ampicillin or penicillin G alone in killing most GBS strains in vitro[298] and in vivo.[322] For suspected late-onset disease, the usual initial therapy includes intravenous ampicillin in combination with cefotaxime or ceftriaxone.[9] If an infant is receiving empirical vancomycin therapy and GBS meningitis has not been excluded, penicillin G or ampicillin should be added to the regimen because vancomycin is inhibitory rather than bactericidal in vitro, and CSF concentrations may not exceed the minimal inhibitory concentration if a high inoculum of GBS is present.[103]

Specific Treatment

Once GBS have been identified in cultures of blood, CSF, or other normally sterile body sites and blood and CSF cultures are shown to be sterile, penicillin G alone should be used to complete therapy. Recommendations concerning the optimal dose and duration have varied, but they

TABLE 83-3 **Treatment of Group B Streptococcal Infections in Infants**

Focus of Infection	Antibiotic	Daily Dose	Duration
Suspected meningitis (initial empirical therapy)	Ampicillin *plus* gentamicin	300-400 mg/kg 7.5 mg/kg	Until cerebrospinal fluid is sterile
Suspected sepsis* (initial empirical therapy)	Ampicillin *plus* gentamicin	150-200 mg/kg	Until bloodstream is sterile
Meningitis	Penicillin G	450,000-500,000 U/kg	14 days minimum†
Bacteremia	Penicillin G	200,000 U/kg	10 days
Arthritis	Penicillin G	200,000-300,000 U/kg	2-3 wk
Osteomyelitis	Penicillin G	200,000-300,000 U/kg	3-4 wk
Endocarditis	Penicillin G	400,000 U/kg	4 wk‡

*Assumes that lumbar puncture has been performed and the cerebrospinal fluid has no abnormalities.
†Should be extended to 21 days or longer if ventriculitis, cerebritis, subdural empyema, or other suppurative complications occur.
‡In combination with low-dose gentamicin for the first 14 days.

should be dictated by the focus and severity of the infection (see Table 83-3). The following issues should be considered when selecting the appropriate dose:

1. The usual minimal bactericidal concentration of penicillin for GBS ranges from 0.04 to 0.8 µg/mL.[185]
2. Only 10 percent of penicillin serum levels reach the CSF.
3. The inoculum of GBS in the CSF of infants with meningitis may reach 10^7 to 10^8 colony-forming units/mL.[116]
4. High doses of penicillin G and ampicillin are safe in neonates.[108]

To ensure rapid bacterial killing, especially in infants with meningitis, relatively high doses of penicillin are recommended for both early- and late-onset infections.

The infant with meningitis should undergo a second lumbar puncture 24 to 48 hours into therapy to document CSF sterility.[103] Infants with continued positive CSF cultures may have very high inoculum, ventriculitis with obstruction, severe infection with cerebritis and vasculitis, subdural empyema, or septic thrombophlebitis, or they may be receiving an insufficient dose of antibiotics; in this circumstance, appropriate studies should be initiated to determine which of these conditions is present. When CSF sterility is verified, penicillin G alone is given for a minimum of 14 days.[9] Longer treatment is indicated if the course is severe, the infant has ventriculitis, or CSF sterilization is delayed. Another lumbar puncture to evaluate CSF cell count and protein should be considered at the anticipated completion of therapy. Findings of polymorphonuclear cells greater than 30 percent or protein higher than 200 mg/dL may warrant further diagnostic evaluation and longer duration of therapy.[103] In addition, a contrast-enhanced neuroimaging study should be performed near completion of therapy in complicated cases, including infants who have prolonged fever (>5 days), cerebritis, abscess(es), subdural empyema, or venous thrombosis. Such complications often correlate with neurologic abnormalities that lead to a poor prognosis for complete central nervous system recovery.[108,344]

Infants with bacteremia without a focus should receive intravenous therapy for a total of 10 days.[9] A shorter duration has not been documented to be efficacious, and relapses, although rare, have been reported in these circumstances.[66,346] Patients with septic arthritis, osteomyelitis, or endocarditis should be treated for the durations summarized in Table 83-3. Oral therapy has no place in the management of infants with GBS disease.[9,107] Alternative agents such as the third-generation cephalosporins and vancomycin are active against GBS in vitro.[118,206] The clinical efficacy of these agents is unknown, however, and these drugs are not recommended in most circumstances.

Supportive Treatment

The importance of prompt, vigorous, and careful supportive therapy in the successful treatment of infant GBS infections cannot be overemphasized. Neonates with early-onset disease accompanied by pneumonia should be suspected of having early respiratory failure, and ventilatory support should be initiated before the onset of apnea, septic shock, or frank respiratory failure occurs. Persistent metabolic acidosis and delayed capillary refill should prompt treatment for shock. All patients with signs of impending respiratory or circulatory failure or meningitis should be treated in an intensive care unit. When present, hypoxemia, severe anemia, and acidosis should be corrected, and seizures should be controlled with anticonvulsants. In addition, fluid and electrolyte status should be monitored meticulously. Surfactant should be used as per nursery protocol; improved gas exchange is seen in infected premature neonates who receive surfactant, although the response is slower than in patients with respiratory distress syndrome.[156] Finally, if an infant has persistent pulmonary hypertension or if conventional ventilatory therapy has failed, extracorporeal membrane oxygenation may be considered, if available.

Adjunctive Treatment

Adjunctive treatment of life-threatening GBS disease is aimed at correcting poor host defenses. Such treatment previously studied includes intravenous human immunoglobulin, monoclonal antibodies to GBS polysaccharide

antigen, leukocyte transfusion, and growth factors such as granulocyte colony-stimulating factor and granulocyte-monocyte colony-stimulating factor for neutropenia.[70,80,133] The efficacy of these agents has not been established, and, although they may be used occasionally, they should be considered experimental.

Recurrent Infections

In the few infants who experience a recurrence, suppurative foci, HIV infection, or humoral immune deficiency should be excluded or treated. Ig levels should be determined to exclude humoral immune deficiency. Although it may be too early to document humoral immune deficiency unequivocally, total IgG usually is significantly lower than would be expected for age in weeks.[139] Tube dilution susceptibility of isolates from the first and recurrent episodes should be determined to ensure in vitro susceptibility to penicillin. If the reason for the recurrence remains unknown, persistent mucous membrane colonization with GBS probably is the source.[247] β-Lactam antibiotics, even when administered by the parenteral route, do not eradicate GBS colonization reliably.[259] Some studies have shown the benefit of rifampin 20 mg/kg/day to eradicate mucosal GBS colonization when given orally during the last 4 days of parenteral therapy.[139,240] However, a more recent study showed failure of rifampin to eradicate GBS colonization in infants.[119]

PROGNOSIS

The outcome of GBS disease is related to the severity and site of infection at initial evaluation. Improved outcomes after early-onset infection have resulted from greater awareness among pediatricians and improved obstetric management. Improvements in obstetrics include the use of intrapartum antibiotic prophylaxis in women at risk for delivering an infant with early-onset GBS infection. However, the mortality rate remains substantial at 2 to 8 percent, especially in neonates born at less than 37 weeks of gestation, in whom the mortality rate often exceeds 20 percent.[76,304]

Little information is available on the long-term prognosis of survivors of GBS sepsis without meningitis. In infants with septic shock, the development of periventricular leukomalacia has been reported and associated with neurodevelopmental sequelae.[112] However, the frequency of this association is not known.

For infants with early- or late-onset meningitis, 20 to 30 percent will have permanent neurologic sequelae, and 20 percent of these impaired survivors have global mental retardation, cortical blindness, hearing loss, spasticity, or paresis.[108,145,199,344] Despite advances in intensive care, a current assessment shows that rates of neurologic impairment remain unchanged.[199] This study evaluated term infants to avoid confounders of cognitive and behavioral deficits related to prematurity.

To date, the prognosis for infants with osteoarticular or soft tissue infections with GBS has been excellent.[23,104] However, omission of early surgical intervention for infections that involve either the hip or shoulder joints can result in epiphyseal injury.

PREVENTION

The continuing magnitude and severity of GBS disease and its attendant mortality and morbidity have led to investigations aimed at its prevention. Several general approaches have been proposed: maternal prophylaxis to decrease transmission, infant prophylaxis to decrease colonization, and immunoprophylaxis to increase protection against disease.

Intrapartum Antibiotic Prophylaxis

Maternal Prophylaxis

Epidemiologic studies during the 1980s showed that women with GBS colonization during pregnancy had more than 25 times likelihood of delivering infants with early-onset disease in contrast to women with negative prenatal cultures.[340,341] The idea to give antibiotic therapy to the mother to prevent vertical transmission to her fetus was suggested first by Franciosi and colleagues.[125] The first strategy to be evaluated was antenatal treatment of GBS maternal carriers with oral or intramuscular penicillin. This method temporarily suppresses colonization density but does not eradicate colonization or interrupt vertical transmission of GBS to neonates.[130,141,280]

The next strategy, maternal intrapartum chemoprophylaxis, has been demonstrated to be efficacious in the prevention of vertical transmission of GBS from colonized mothers to their neonates, the development of early-onset disease, and maternal febrile morbidity. Infants are less frequently colonized with GBS if they are born to mothers treated with ampicillin during labor than to mothers not given antibiotics.[60,61,365] Several controlled trials involving thousands of deliveries indicated that intrapartum penicillin G or ampicillin given intravenously to GBS carriers during labor prevents early-onset disease in neonates.[58,231,333] Early-onset infection occurred in 0 to 1.1 percent of infants whose mothers received intrapartum ampicillin in contrast to 5 to 9 percent of infants of mothers in the groups not receiving prophylaxis. A large trial involving more than 50,000 live births in Australia showed similar results.[131]

In 1996, guidelines supported by the Centers for Disease Control and Prevention (CDC), the American College of Obstetricians and Gynecologists, and the American Academy of Pediatrics recommended a risk-based or culture-based approach.[341] The risk-based approach was based on the presence of one or more of the following: premature labor at less than 37 weeks of gestation, prolonged rupture of membranes (>18 hours), GBS bacteriuria, intrapartum fever (38°C [≥100.4°F]) or delivery of a previous infant with GBS infection. The culture-based approach required intrapartum chemoprophylaxis for all women with positive vaginal and rectal cultures routinely obtained at 35 to 37 weeks of gestation regardless of risk factors. Use of these methods to define women who were candidates for intrapartum

chemoprophylaxis led to a 70 percent decline in the incidence of early-onset GBS disease.[302,341]

In 2002, a population-based study compared the two approaches and found the culture-based approach to be 50 percent more effective than the risk-based approach in preventing early-onset GBS disease.[303] Sixty-two percent of infants with early-onset disease were born to mothers who did not have any clinical risk factors. Therefore, revised guidelines published by the CDC in 2002 recommended universal vaginal and rectal screening cultures of all pregnant women between 35 and 37 weeks of gestation, with intrapartum chemoprophylaxis for all women identified as GBS carriers.[301] The risk-based approach was to be reserved for any women in labor whose colonization status is unknown. After release of these guidelines, active population surveillance showed that 85 percent of women were being actively screened, resulting in a 27 percent further decline in incidence of early-onset infection.[340] However, the retrospective cohort study also revealed missed opportunities for screening and chemoprophylaxis for women with unknown colonization status, especially those at risk for preterm delivery. Unpublished data from the CDC showed that antibiotic prophylaxis was 78 percent effective in preventing early-onset infection in preterm infants.[341] Thus, revised intrapartum chemoprophylaxis guidelines with specific algorithms for women with preterm labor or premature rupture of membranes were released in 2010.[341] If a woman with unknown colonization status is admitted with signs and symptoms of preterm labor or premature rupture of membranes, vaginal and rectal swabs should be obtained for culture and intrapartum chemoprophylaxis should be started and continued until delivery. If amniotic membranes are intact, prophylaxis should be discontinued if it is determined that the woman is not in true labor. Women with premature rupture of membranes who are not in labor should continue antibiotics per standard of care if receiving to prolong latency or continue antibiotics for 48 hours if receiving for GBS prophylaxis.

Colonization or bacteriuria during a previous pregnancy is not an indication for intrapartum chemoprophylaxis. Intrapartum chemoprophylaxis also is not indicated for cesarean section performed before onset of labor on a woman with intact amniotic membranes, regardless of GBS colonization status or gestational age. Women with GBS isolated from urine at a concentration of 10^4 colony-forming units/mL or greater during the current pregnancy should receive intrapartum chemoprophylaxis, because these women usually are heavily colonized. Women who previously gave birth to an infant with invasive GBS disease always should receive chemoprophylaxis. Table 83-4 shows the indications and nonindications for intrapartum chemoprophylaxis according to the current guidelines (released in 2010).[341]

Optimal culture techniques are discussed earlier in the chapter. Many rapid tests are being studied because they offer the advantage of detecting colonization status in women who present for preterm labor or who have not had prenatal care. These tests include latex agglutination, optical immunoassay, DNA hybridization, enzyme immunoassay, Islam starch medium tests, and PCR.[160] With the exception of PCR, all tests showed poor sensitivity or specificity in contrast to the standard culture method and are not sufficiently accurate to replace routine culture in decision making concerning intrapartum antibiotic prophylaxis. A multicenter study evaluated a real-time PCR assay that gave results in 40 minutes.[88] In contrast to intrapartum culture, the PCR assay had a sensitivity of 94 to 98 percent and a specificity of 96 to 99 percent.[88,110] Nucleic acid amplification tests, such as commercially available PCR assays, are an option for intrapartum testing for women who have unknown colonization status at labor onset.[341] However, these tests

TABLE 83-4 **Indications and Nonindications for Maternal Intrapartum Prophylaxis to Prevent Early-Onset Group B Streptococcal Infection**

Intrapartum GBS Prophylaxis Indicated	Intrapartum GBS Prophylaxis Not Indicated
Previous infant with invasive GBS disease	Colonization with GBS during a previous pregnancy
GBS bacteriuria during any trimester of current pregnancy*	GBS bacteriuria during previous pregnancy
Positive GBS vaginal-rectal screening culture within preceding 5 weeks*	Negative vaginal and rectal screening culture, regardless of intrapartum risk factors
Unknown GBS status at onset of labor and any of the following: Delivery at <37 weeks of gestation Prolonged rupture of membranes for ≥18 hr Intrapartum temperature ≥100.4°F (38°C)† Intrapartum NAAT positive for GBS‡	Cesarean delivery performed before onset of labor on a woman with intact amniotic membranes, regardless of GBS colonization status or gestational age

Modified from Centers for Disease Control and Prevention: Prevention of perinatal group B streptococcal disease: revised guidelines from CDC, 2010. *MMWR Morb Mortal Wkly Rep* 2010;**59**:1-32.

*Intrapartum chemoprophylaxis is not indicated in this circumstance if a cesarean delivery is performed before onset of labor on a woman with intact membranes.

†If amnionitis is suspected, broad-spectrum antibiotic therapy that includes an agent active against GBS should replace GBS prophylaxis.

‡GBS NAATs are optional and may not be available in all settings (see text). If intrapartum NAAT is negative for GBS but any other of these intrapartum risk factors is present, intrapartum GBS prophylaxis is indicated.

GBS, Group B streptococcus; *NAAT,* nucleic acid amplification test.

should not replace antenatal culture- or risk-based assessment of women with unknown colonization status. Nucleic acid amplification tests must be performed on samples placed in selective enrichment broths for adequate sensitivity of the assay, thereby lengthening the turnaround time and making it less useful in the real-world setting at this time.

Maternal chemoprophylaxis begins at hospital admission for delivery or at rupture of membranes and consists of intravenous penicillin G (initial dose, 5 million U; subsequent doses, 2.5 to 3 million U every 4 hours until delivery).[303,341] Although penicillin is preferred because of its narrow spectrum of activity, ampicillin (initial dose, 2 g; subsequent doses, 1 g every 4 hours) can be given as an alternative. For women who are allergic to penicillin, intrapartum chemoprophylaxis must take into account increasing resistance rates to clindamycin and erythromycin.[56,91] Women at low risk for developing anaphylaxis should be given cefazolin (initial dose, 2 g; subsequent doses, 1 g every 8 hours). Women at high risk for developing anaphylaxis should have susceptibility testing performed on their isolates obtained during screening at 35 to 37 weeks of gestation. Susceptibility testing should include checking for inducible clindamycin resistance. If the isolate is susceptible, clindamycin 900 mg every 8 hours can be used. Erythromycin is no longer an acceptable alternative.[341] If susceptibility testing is not available, the results are not known, or the isolate is resistant to clindamycin, vancomycin 1 g every 12 hours can be given as the alternative. The efficacy of vancomycin is not known.

Since the widespread adoption of chemoprophylaxis, the incidence of early-onset disease has plummeted.[302,340,341] Racial disparities in early-onset disease have declined significantly,[302] but the higher incidence of early-onset infection in black infants in contrast to nonblack infants remains a problem. Opportunities to prevent early-onset disease still are missed, however, because of laboratory practices,[74] hospital or procedural errors in communication of the screening results, failure to administer intrapartum chemoprophylaxis to a mother known to be colonized, or failure to recognize preterm delivery in mothers with unknown colonization status as an indication for prophylaxis.[279,340] The incidence of late-onset disease remains unaffected by intrapartum chemoprophylaxis.[175,341]

Management of an infant born to a mother given intrapartum prophylaxis depends on the clinical findings at birth, antibiotic regimen, and timing of doses administered to the mother (Figure 83-6). Amniotic fluid levels of penicillin that will kill GBS are not achieved until at least 3 hours after administration of the first dose.[63] If the infant of any gestational age appears healthy and has a mother who received at least one dose of intrapartum chemoprophylaxis with intravenous penicillin, ampicillin, or cefazolin at least 4 hours before delivery, neither diagnostic evaluation nor empirical antimicrobial therapy is required.[341] However, to ensure their ongoing stability, such infants should be observed in the hospital for at least 48 hours. Keeping the infant hospitalized through the second day of life has been challenging because the associated expense affects the cost-to-benefit ratio of intrapartum prophylaxis.[244] However, an analysis of all live births in the state of Florida for the years 1992 through 1994 demonstrated a 115 percent increase in the rate of readmission for GBS infection in infants discharged on the first day of life; this finding supports the recommendation to observe infants for 48 hours.[137]

Neonates with signs of sepsis are evaluated and treated empirically for sepsis. Healthy-appearing neonates born at 37 weeks of gestation or later to a mother with an indication for chemoprophylaxis but who had received inadequate intrapartum chemoprophylaxis should be observed at least 48 hours. An infant born at less than 37 weeks of gestation or after membrane rupture for 18 hours or longer to a mother with inadequate chemoprophylaxis should undergo limited laboratory evaluation (i.e., complete blood count and blood culture) and observation in the hospital for 48 hours without therapy. Adequate intrapartum chemoprophylaxis is defined as at least 4 hours of intravenous penicillin, ampicillin, or cefazolin. All other agents are considered inadequate.[341] If the subsequent clinical course or the laboratory results suggest infection, full diagnostic evaluation and therapy are initiated.

Concern that widespread use of intrapartum ampicillin use will result in a greater incidence of ampicillin-resistant neonatal infection has been supported by some case series.[51,178,237] Development of penicillin- or ampicillin-resistant GBS has not been seen.[79] In most studies, incidence rates of *E. coli* and other gram-negative pathogens have remained stable.[4,178,237,290] The rate of ampicillin-resistant *E. coli* infections is increasing in preterm infants. However, rates of ampicillin resistance in term neonates before and after widespread intrapartum chemoprophylaxis are the same.

Infant Chemoprophylaxis

The two controlled trials evaluating neonatal prophylaxis reached contradictory conclusions.[280,311] In the first trial, more than 16,000 newborns received either intramuscular penicillin G or topical tetracycline (prophylaxis for gonococcal ophthalmia neonatorum) within an hour of birth during alternating weeks.[311] In penicillin-treated newborns, the incidence of proved early-onset GBS disease was less common, but death rates were similar, and an increase in the number of penicillin-resistant infections in the penicillin group was noted. In the second controlled study, blood cultures were obtained before initiation of penicillin therapy, and rates of GBS bacteremia were similar in the treatment and control groups.[280] In this study of nearly 1200 neonates weighing 2000 g or less at birth, intramuscular penicillin (or no treatment) was given in the first hour of life and was continued for 3 days. Rates of GBS bacteremia were similar in the treatment and control groups. Penicillin prophylaxis probably was ineffective because almost 90 percent of neonates with early-onset GBS disease were bacteremic immediately after birth. The results of the second study are supported by numerous observations, thus indicating that early-onset disease often begins in

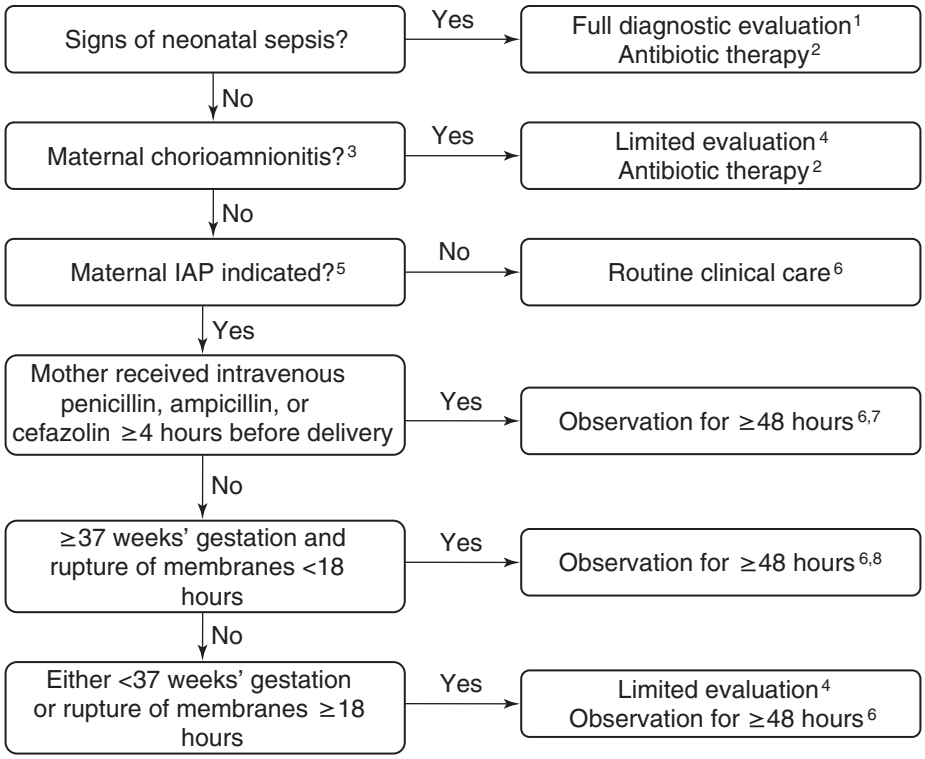

FIGURE 83-6 ■ Empirical management of a newborn for secondary prevention of early-onset group B streptococcal infection.
[1]Includes complete blood cell count (CBC) and differential, blood culture, and chest radiograph if respiratory abnormalities are present. When signs of sepsis are present, a lumbar puncture, if feasible, should be performed.
[2]Antibiotic therapy should be directed toward common causes of neonatal sepsis, including ampicillin for group B *Streptococcus* and coverage for *Escherichia coli* and other gram-negative pathogens, and should take into account local resistance patterns.
[3]Consultation with obstetric providers is important to determine the level of clinical suspicion for chorioamnionitis. Chorioamnionitis is diagnosed clinically, and some of the signs are nonspecific.
[4]Includes complete CBC and differential and blood culture.
[5]See Table 83-4 for indications for maternal intrapartum prophylaxis.
[6]If signs of sepsis develop, a full diagnostic evaluation should be conducted and antibiotic therapy initiated.
[7]A healthy-appearing infant who was ≥37 weeks of gestation at delivery and whose mother received ≥4 hours of appropriate intrapartum antibiotic prophylaxis (*IAP*) before delivery may be discharged home after 24 hours if other discharge criteria have been met, a person able to comply fully with instructions for home observation will be present, and access to medical care is readily available. If any one of these conditions is not met, the infant should be observed in the hospital for at least 48 hours and until criteria for discharge are achieved.
[8]Some experts recommend a CBC with differential at 6 to 12 hours. (Modified from the Centers for Disease Control and Prevention. Prevention of perinatal group B streptococcal disease—revised guidelines from CDC, 2010. *MMWR Morb Mortal Wkly Rep* 2010;59:1-32.)

utero.[61,262,305] Infant chemoprophylaxis currently is not recommended.[341]

Immunoprophylaxis

Although efforts to improve implementation of intrapartum chemoprophylaxis are ongoing, the most promising and potentially lasting method for prevention of both early- and late-onset infant infections is immunoprophylaxis. This approach remains investigational, and several reviews have summarized the rationale.[26,147,257] It is based on the observation that immunity to GBS correlates with antibody directed against the type-specific capsular polysaccharides of these organisms. These IgG class antibodies and complement promote opsonization, phagocytosis, and bacterial killing of GBS and protect animals against lethal challenge.[258,353] Thus, provision of protective levels of type-specific immunity to the infant could be achieved through active immunization of the mother. Baker and associates[37] immunized women at a mean gestation of 31 weeks with purified type III polysaccharide vaccine. Although the immune response was not optimal (63%), placental transport of maternal antibodies occurred in 90 percent in neonates born to women who did respond to vaccination, and most of these infants had protective levels of antibodies in their sera at 3 months of age. A more recent study immunizing women with a type III polysaccharide-tetanus toxoid conjugate reported a 95 percent immune response, with persistence of opsonophagocytic antibodies at 2 months of age in 100 percent of infants born to maternal responders.[27] Other studies immunizing nonpregnant adults with purified capsular polysaccharide–tetanus toxoid conjugate vaccines showed the safety and immunogenicity of these vaccines.[35,36,38]

Availability of the complete genome sequences for GBS has led to the discovery of many potential surface proteins and secreted proteins that can be expressed in

recombinant form and used for production of antibodies.[217,329] A set of proteins shared by the disease-causing serotypes theoretically can be used in combination to create a vaccine capable of providing protection against multiple serotypes. GBS pili with at least one of the pilus islands present in all sequenced GBS genomes may be included in a future vaccine.[67,171]

Because most pregnant women (estimated at 85% to 90%) have nonprotective levels of these antibodies in their sera at delivery, active immunization of childbearing-age women before or during pregnancy would optimize strategy to induce high maternal antibody levels. Human studies have demonstrated efficient antibody transfer to the neonate.[30,37] Transfer of high levels of maternal antibody would provide protection of the neonates from early- and late-onset GBS.[176] In addition, immunization also would offer protection for the mother against preterm deliveries and fetal loss caused by GBS infection. Finally, vaccination of elderly or nonpregnant adults with defined medical conditions could reduce the disease burden significantly. Because immunoprophylaxis should be the most cost-effective and beneficial prevention strategy for GBS disease,[148,245,313] it should be promoted by physicians, public health officials, parents, pharmaceutical manufacturers, and legislators.

CHAPTER 84

Enterococcal and Viridans Streptococcal Infections

B. Keith English • Jerry L. Shenep

ENTEROCOCCAL INFECTIONS

The enterococci are gram-positive ovoid bacteria that are related closely to the streptococci but are phylogenetically distinct and make up the genus *Enterococcus*. These organisms are found in the normal bowel flora of humans and many animals and commonly are isolated from environmental sources. Enterococci generally are considered to be of low virulence but have been known to cause human infection since 1899 (reviewed by Murray[182]). These ubiquitous bacteria have become recognized increasingly as important causes of both nosocomial and community-acquired infection in adults* and children,† yet the role of *Enterococcus* spp. as a pathogen (or co-pathogen) in certain clinical settings, particularly intra-abdominal and pelvic infections, often remains unclear.

Enterococci are intrinsically resistant to many antimicrobial agents (including the cephalosporins, oxacillin, clindamycin, and the aminoglycosides). Since the emergence of high-level aminoglycoside resistance in *Enterococcus* spp. more than 40 years ago,[174] increasing percentages of these organisms have acquired clinically significant resistance to β-lactam antibiotics, vancomycin and other glycopeptides, and aminoglycosides. Vancomycin-resistant enterococcal (VRE) infections, especially those caused by vancomycin-resistant *Enterococcus faecium* (VREF), are of particular concern because VREF isolates frequently are resistant to other bactericidal antimicrobial agents.[4,184,186,233] The dramatic increase in nosocomial VRE infections[4,65,184,198] has resulted in failure of antimicrobial therapy[138] and has inspired comparisons with the preantibiotic period[5] and even speculation about a "postantimicrobial era."[46] Fortunately, new classes of antimicrobials active against most VRE isolates have become available recently, but pediatric experience with these agents is limited, and enterococci resistant to these agents already have been detected (see later discussion). Concern about the continued nosocomial spread of VRE isolates and the documented transfer of vancomycin resistance determinants to *Staphylococcus aureus*[29,30,264,274] led to the development of stringent hospital infection control guidelines designed to interrupt the spread of vancomycin-resistant organisms.[193] Although the impact of VRE infections in children has been less dramatic, many pediatric centers are reporting infections caused by these organisms.*

MICROBIOLOGY

The genus *Enterococcus* consists of gram-positive cocci that are catalase-negative and occur singly, in pairs, and in short chains. Morphologically, enterococci are indistinguishable from streptococci and traditionally were classified as members of the genus *Streptococcus*. Sherman's early classification scheme[243] divided the streptococci into four groups: pyogenic, viridans, lactic, and enterococcal. By the Lancefield criteria, enterococci were classified as group D streptococci, along with the "nonenterococcal" *Streptococcus bovis* group. However, genetic evidence has indicated that the enterococci are sufficiently different from the streptococci to merit establishment of a separate genus.[70]

Figure 84-2 is a scheme for the differentiation of enterococci from other gram-positive cocci. Catalase-negative gram-positive cocci that have been isolated from human sources include the streptococci, the enterococci, *Lactococcus* spp., *Leuconostoc* spp., *Pediococcus* spp., and *Gemella* spp. Most enterococci produce no (γ) or partial (α) hemolysis on blood agar; differentiation between enterococci and certain α-hemolytic or nonhemolytic streptococci and other nonstreptococcal gram-positive cocci may require a series of biochemical tests.[70,71] Clinical laboratories may identify an organism presumptively on a primary isolation plate as an enterococcus based on colony morphology, Gram stain, and the pyrrolidonyl arylamidase (PYR) test. Most enterococci produce PYR, as do *Streptococcus pyogenes* and nutritionally variant streptococci *(Abiotrophia)*, but not other streptococci. The PYR test is particularly useful for differentiating

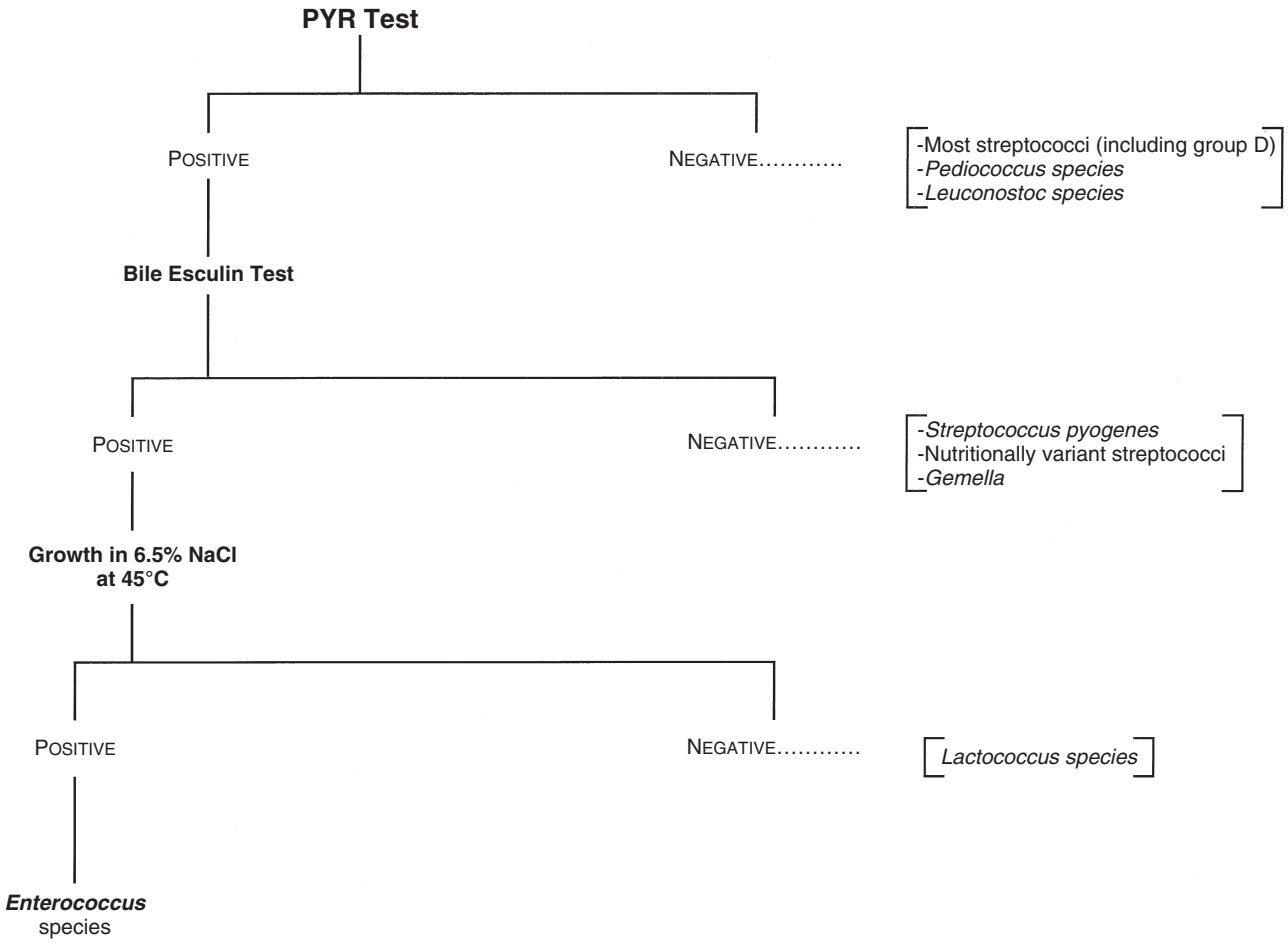

FIGURE 84-1 ■ Differentiation of enterococci from other gram-positive cocci. *PYR,* pyrrolidonyl.

enterococci from group D streptococci and *Leuconostoc* spp. (see Fig. 84-1). *S. pyogenes* and *Abiotrophia* spp. are distinguished easily from enterococci by colony morphology, hemolysis, and special growth requirements.

Enterococci are able to hydrolyze esculin in the presence of 40 percent bile salts; of the true streptococci, only group D streptococci (*S. bovis* group) and approximately 5 to 10 percent of viridans streptococci share this characteristic.[70] Enterococci are facultatively anaerobic and grow under harsh conditions that inhibit the growth of streptococci; growth in 6.5 percent sodium chloride at 45° C (113° F) is a useful confirmatory test. Enterococci produce leucine aminopeptidase, as do streptococci, lactococci, pediococci, and some *Gemella* strains. The presence of group D streptococcal antigen is of limited value because the *S. bovis* group, most pediococci, and half of the clinical *Leuconostoc* spp. isolates share this antigen.[70]

Occasional clinical isolates of *Leuconostoc* spp., *Pediococcus* spp., and *Lactococcus* spp. may be difficult to distinguish from the enterococci. Some strains of *Leuconostoc* spp. and *Pediococcus* spp. may grow in 6.5 percent NaCl at 45° C, but they are PYR-negative. Lactococci are PYR-positive, and some isolates will grow in 6.5 percent NaCl; however, most lactococci fail to grow (or grow very slowly) at 45° C. Consequently, definitive confirmation of an organism as an enterococcus may require complete identification to the species level. Molecular techniques allow rapid, reliable identification and speciation of enterococci,[52,59,63] but usually are available only in the research setting.

The genus *Enterococcus* now includes at least 14 "typical" species and 3 additional "atypical" species (the latter are PYR-negative and grow very slowly in the presence of 6.5% NaCl) (Table 84-1). However, most human clinical isolates are either *Enterococcus faecalis* (50% to 90%) or *E. faecium* (5% to 37% percent), although clusters of human infection caused by *Enterococcus raffinosus*,[35] *Enterococcus casseliflavus*,[191] *Enterococcus avium*,[203] and *Enterococcus durans*[237] and occasional human infections attributable to *Enterococcus gallinarum*, *Enterococcus mundtii*, and *Enterococcus flavescens* have been reported.[69] Even though *E. faecalis* and *E. faecium* continue to account for most clinical isolates, the percentage of *E. faecium* isolates has been increasing, and relatively more "other" (i.e., non-*faecalis* and non-*faecium*) enterococci are being identified by clinical laboratories.[121,123,153]

Speciation of enterococci has been useful primarily for epidemiologic purposes, but distinction between the more antibiotic-susceptible *E. faecalis* and the more antibiotic-resistant (see later discussion) *E. faecium* may be helpful in selecting optimal therapy for endocarditis

and other serious enterococcal infections. A panel of biologic tests can differentiate these two common enterococcal species readily.[70,129,182] Most *E. faecalis* isolates (unlike those of *E. faecium*) grow in the presence of 0.04 percent tellurite, reduce tetrazolium to formazan, and produce acid from sorbitol and glycerol.

A variety of molecular techniques are available to assist in the identification of enterococci and determination of the relatedness of enterococcal isolates.* These molecular techniques have been particularly valuable in investigations of possible nosocomial transmission of multiresistant enterococci.†

EPIDEMIOLOGY

Enterococci are normal flora of the gastrointestinal tract of most humans and have been found in as many as 97 percent of fecal samples from adults in Europe, Asia, and North America (reviewed by Murray[182]). Approximately half of newborn infants have become colonized with enterococci by the time they are 1 week of age.[194] Enterococci are isolated less commonly (<20% of specimens) from other sites, including the vagina, oral cavity, and skin. These organisms also are common inhabitants of the bowel flora of many animals and frequently are present in soil, water, and food. Enterococci are hardy organisms and may persist for long periods on environmental surfaces, thereby contributing to potential nosocomial spread of these bacteria.

Human infection caused by enterococci was reported before the beginning of the 20th century, but the initial reports included patients with infections that seldom are associated with enterococci today: enteritis, meningitis, and appendicitis (reviewed by Murray[182]). The ubiquitous presence of enterococci in fecal samples led to the mistaken impression that these organisms cause enteritis and food poisoning. Enterococci are isolated commonly as part of mixed flora in intra-abdominal and pelvic infections, but the contribution of these organisms to the pathogenesis of such infections remains unclear.[88,192] However, enterococci were identified as pathogens causing urinary tract infection and endocarditis as early as 1906,[4] with later confirmation by many studies. Subsequently, enterococci have been documented to cause invasive infection in neonates,* patients with malignancies,† recipients of bone marrow and solid organ transplants,‡ burn victims,[140] patients with indwelling catheters,§ and other immunosuppressed or debilitated patients.‖

In general, enterococcal infections occur less frequently in children (outside the neonatal period) than in adults, and enterococci are less common causes of pediatric (vs. adult) urinary tract infection[282] and endocarditis.[253] Much of the published experience with enterococcal infection in children focuses on the neonatal period,¶ and some evidence suggests that late-onset (but not early-onset) neonatal enterococcal infection may be increasing in frequency.[41,58] Relatively few series of pediatric enterococcal infection have been published.**

Enterococci are important nosocomial agents, and they rank as either the second or third most common hospital-acquired pathogens in this country.†† Evidence of nosocomial spread of enterococci is relatively recent. Initially, all enterococci isolated from hospitalized patients were thought to have originated from the patient's endogenous bowel flora. However, the emergence of multiantibiotic-resistant enterococci prompted the performance of careful epidemiologic studies that documented the nosocomial spread of these organisms.†† Many groups have reported that VRE and other enterococcal isolates may persist for long periods in the environment and may be spread either by direct patient-to-patient contact via the hands of colonized health care personnel[214] or from contaminated beds or other hospital material or contaminated patient equipment, including thermometers.[4,19,128,145,171]

The growing problem of nosocomial infection by VRE organisms is multifactorial; the diversity of isolates found in many hospitals indicates that resistant organisms may be introduced via multiple sources.‡‡ Consequently, outbreaks of VRE infection in institutions may be caused by single or multiple clones, although the first recognized outbreak of VRE infection or colonization in a hospital usually is associated with a single clone.[32,85]

In many reports, distinguishing risk factors for VRE colonization from those for invasive disease caused by these organisms has not been possible, and certain factors probably increase the risk for both colonization and development of infection caused by VRE organisms. Major risk factors for VRE colonization or the development of infection, or for both, appear to be the severity of the underlying illness or immunosuppression; the proximity to patients colonized with VRE organisms (e.g., admission to an intensive care unit [ICU] or a transplant unit); receipt of a bone marrow or solid organ (especially liver) transplant; increasing length of hospital stay; recent cardiothoracic or abdominal surgery; the presence of indwelling central venous or urinary catheters; and previous treatment with vancomycin, broad-spectrum antibiotics (particularly those lacking appreciable antienterococcal activity, such as the third-generation cephalosporins), or agents with broad antianaerobic activity.* Patients infected with human immunodeficiency virus (HIV) also appear to be at higher risk for the development of VRE bacteremia.[10] Factors contributing to nosocomial spread of these organisms probably differ from those responsible for the gradual overall increase in resistant strains.[217]

Since the first report of a vancomycin-resistant isolate in 1988,[141] infection and colonization with VRE bacteria in the United States have been observed primarily in the ICUs of large teaching hospitals.[28,184,186] For example, data reported to the National Nosocomial Infection Surveillance (NNIS) system of the Centers for Disease Control and Prevention (CDC) from January 1989 through March 1993 revealed no vancomycin resistance in hospitals with fewer than 200 beds, a resistance rate of 1.8 percent in hospitals with 200 to 500 beds, and a rate of 3.6 percent in hospitals with more than 500 beds.[28] A 1995 report from the multicenter *Enterococcus* Study Group analyzed 1936 isolates collected from 97 laboratories in 47 states during the last quarter of 1992 and generally confirmed the findings of the NNIS survey.[121] However, VRE infections are not limited to ICUs. A 1999 report from the Surveillance and Control of Pathogens of Epidemiologic Importance (SCOPE) group's ongoing surveillance of nosocomial bloodstream infections in 49 U.S. hospitals revealed no overall differences in rates of vancomycin resistance in enterococci isolated from patients located in critical care versus hospital ward settings.[65] Fortunately, VRE infections have occurred much less frequently in children than in adults, and overall rates of vancomycin resistance in enterococci isolated from children's hospitals remain very low. However, many pediatric centers have reported VRE infections.†

In the United States, VRE isolates generally have not been detected in environmental sources or in patients who have not had exposure to hospitals,[182,184] with rare exceptions.[32] However, the ecology of VRE organisms in Europe differs: they have been detected in the feces of nonhospitalized patients and healthy volunteers in several European studies, with rates of VRE colonization as high as 28 percent in adults living in some parts of Belgium (reviewed by Murray[182,184]). The more widespread occurrence of VRE strains in Europe probably was related to the use of oral glycopeptides such as avoparcin in animal feed and the oral administration of bacterial preparations (possibly contaminated with resistant enterococci) to humans and animals for therapeutic purposes.[182-184]

Initial reports of VRE organisms in the United States were clustered in the northeast region, particularly New York, Maryland, and Pennsylvania,[28] and geographic differences in rates of VRE colonization and infection persist. However, subsequent reports indicate that VRE strains are found in most parts of the United States[120,153] and that rates of vancomycin resistance among enterococci isolated from patients in this country generally are higher than those found in isolates from Canada, Western Europe, or Latin America.[119,122,153] The reasons for these geographic differences remain unclear, but the high rates of resistance in the United States may be related to the increased use of vancomycin in this country during the past 3 decades.[132]

PATHOGENESIS AND VIRULENCE

Enterococci are organisms of low virulence, and their ubiquitous presence in the human gastrointestinal tract probably has contributed to both the spurious association of these organisms with some illnesses (e.g., enteritis) and the failure to recognize other situations in which enterococci are true pathogens (e.g., immunosuppressed and debilitated patients and neonates). When contrasted with organisms such as *S. pyogenes* and *S. aureus*, enterococci are much less virulent in animal models of infection,[115,170] but they are capable of causing disease at a higher inoculum.

Enterococci rarely cause primary cellulitis or abscesses, although these organisms are isolated frequently as components of polymicrobial wound infections and intra-abdominal and pelvic infections. The contribution of enterococci to the pathogenesis of these polymicrobial infections remains uncertain.[88,192] In animal models, synergy between enterococci and a variety of other organisms (particularly anaerobes) can be demonstrated, but enterococci injected alone have little propensity to cause either peritonitis or subcutaneous infection.[115,116,182,200] Many clinical trials have concluded that provision of antienterococcal therapy generally is not necessary to effect a cure of human intra-abdominal and pelvic infections, even though *Enterococcus* frequently (14% to 33% of cases) is isolated from primary peritoneal cultures.[88]

Enterococci are an important cause of urinary tract infections in adults (particularly in elderly men, patients with structural abnormalities of the urinary tract, and those with indwelling urinary catheters), but they are associated less frequently with urinary tract infections in children.[8,282] Enterococci also are important but less frequent (than in adults) causes of bacterial endocarditis in children.[166,254]

Adherence of bacteria to tissue is a necessary first step in the pathogenesis of both urinary tract infection and endocarditis, and evidence suggests that pathogenic

*References 11, 12, 42, 95, 214, 217, 220, 222, 250, 285.
†References 15, 18, 48, 58, 84, 133, 154, 163, 214, 247.

enterococci produce factors that mediate adherence to urinary epithelial cells and endocardial tissue (reviewed by Jett and colleagues[115] and Johnson[116]). Enterococcal adhesins include an enterococcal surface protein known as aggregation substance[38,136] and surface carbohydrates. Lipoteichoic acid, an important adhesin for *S. pyogenes*, does not appear to mediate adherence of enterococci,[249] but it may trigger the host inflammatory response to these organisms.[261] The innate immune response to enterococci is poorly understood, though one report has implicated the intracellular sensor nod2 in mediating the host inflammatory response to these organisms.[130] Recent studies have implicated an enterococcal surface protein, Esp, in biofilm formation by *E. faecalis*.[26,263] In addition, many virulent *E. faecalis* isolates express a cytolysin in the presence of target cells.[45,50]

Nosocomial enterococcal bacteremia in adults frequently is associated with urinary tract and wound infections, but catheter-related bacteremia is of increasing importance. Enterococcal bacteremia without a source occurs relatively more commonly in children,[18,217] although Bonadio[15] reported that many children with enterococcal bacteremia had an identifiable focus of infection. Enterococcal bacteremia occurs more frequently in patients with severe underlying disease and may be life-threatening. However, the precise contribution of enterococcal bacteremia to morbidity and mortality in severely ill patients remains unclear in individual patients. Adult ICU patients with enterococcal bacteremia have a very high mortality rate,[90] and some early studies suggested that isolation of *Enterococcus* from blood merely served to identify a very high-risk group of patients.[182] In several studies, clearance of VRE organisms from blood was not associated with a reduced mortality rate in this high-risk population. In other studies, spontaneous resolution of VRE bacteremia has been reported, thus suggesting that transient VRE bacteremia or pseudobacteremia (or both) may occur.[269] However, a series of subsequent studies clearly associated vancomycin resistance with an increased risk for mortality in certain patients and has demonstrated that effective anti-enterococcal therapy reduces the overall mortality rate in patients with VRE bacteremia.* Taken together, these findings indicate that at least a subset of high-risk patients with VRE bacteremia are at risk for the development of significant morbidity and mortality directly related to the infection.

CLINICAL MANIFESTATIONS

Enterococcal infections generally occur less frequently in children than in adults, but *Enterococcus* is a relatively frequent cause of neonatal infections.[58] The types of infections caused by enterococci in children are similar to those in adults,[15,18,53,98,217] although enterococcal bacteremia may be associated with fewer sequelae in children.[53] In children, as well as in adults, enterococci have become increasingly important nosocomial pathogens.† They are important causes of endocarditis, urinary tract infection, and bacteremia (particularly catheter-related bacteremia) in pediatric patients, and these organisms commonly are isolated as components of polymicrobial wound, intra-abdominal, and pelvic infections in children.[15,18,171,182] Meningitis[257] and septic arthritis[212] are rare manifestations of enterococcal infection. Enterococci are also important causes of peritonitis in children being treated with peritoneal dialysis.[257] Respiratory tract infections caused by enterococci are rarely recognized, though many neonates with enterococcal infection have pulmonary symptoms.[58]

Urinary Tract Infection

Urinary tract infections are the most common enterococcal infections in adults,[4,171] and enterococci are important urinary pathogens in children.[7,54,158] Most enterococcal urinary tract infections occur in elderly men after they have undergone urinary catheterization, instrumentation, or both.[73,180] Enterococci are infrequent (<5% of isolates) causes of cystitis and pyelonephritis in otherwise healthy children, infants, and neonates[7,282] and are infrequent causes of urinary tract infection in young women.[182] However, some centers are reporting an increasing incidence of both community-acquired and nosocomial urinary tract infection caused by enterococci.[73]

Most enterococcal urinary tract infections in children[7,54,147] and adults[73,81] are nosocomial. Risk factors for the development of urinary tract infection by *Enterococcus* include indwelling urinary catheters, instrumentation of the urinary tract, structural abnormalities of the urinary tract, and previous broad-spectrum antimicrobial therapy.[180,182] The increasing problem of nosocomial enterococcal urinary tract infection[73] is compounded by the growing problem of multiantibiotic-resistant enterococci.[28]

The genitourinary tract reportedly is the most common entry site leading to enterococcal bacteremia in adults,[90,137] but it is implicated much less frequently in the cause of enterococcal bacteremia in children.[15,18,53] Christie and colleagues[41] reported that urosepsis was the cause of 12 percent of episodes of nosocomial enterococcal bacteremia in one children's hospital, but Das and Gray[53] failed to detect any cases of urosepsis in 75 consecutive cases of enterococcal bacteremia in another pediatric hospital during a 3-year period. Other complications of enterococcal urinary tract infection in adults include prostatitis and perinephric abscess.[171]

Endocarditis

Enterococcal endocarditis was reported first in 1906,[3] and these organisms are important causes of native-valve and prosthetic-valve endocarditis in children and adults.[1,3,166,218] Either normal or previously damaged valves may be involved. Enterococci cause approximately 5 to 20 percent of cases of native-valve endocarditis in adults (excluding cases in intravenous drug users),[166] approximately 6 to 7 percent of prosthetic-valve endocarditis,[166,266] and approximately 5 to 10 percent of endocarditis in intravenous drug users.[182] Enterococcal

*References 55, 56, 64, 107, 184, 205.
†References 18, 28, 41, 62, 77, 78, 98, 135, 163, 170, 196, 220, 285.

endocarditis in intravenous drug users generally involves the aortic or mitral valves, unlike staphylococcal endocarditis in this setting, which usually involves the tricuspid valve.[182] As with other enterococcal infections, *E. faecalis* causes most cases of endocarditis.

Enterococcal endocarditis primarily is a disease of older men, and the genitourinary tract is the most commonly identified source of the initial bacteremia. Enterococci are relatively less frequent causes of endocarditis in children—less than 5 percent of cases in most series.* Typically, enterococcal endocarditis occurs after a subacute course that is clinically indistinguishable from that caused by streptococci.[166] Although the enterococcus is a common neonatal pathogen,[58] reports of neonatal enterococcal endocarditis are extremely rare.[262] The prognosis of enterococcal prosthetic-valve endocarditis is somewhat better than that of native-valve endocarditis caused by these organisms.[1,218] Aortic-valve involvement is associated with increased rates of morbidity and mortality.[166] Endocarditis rarely complicates nosocomial enterococcal bacteremia.[156,182,205] Consequently, VRE-associated endocarditis is a rare development, although cases have been reported.[255]

Bacteremia

Enterococcal bacteremia often represents a conundrum. Bacteremia in severely ill hospitalized patients, particularly that caused by VRE organisms, is associated with considerable morbidity and mortality. However, only a portion of that morbidity and mortality can be attributed directly to enterococcal bacteremia per se. Nosocomial enterococcal bacteremia frequently occurs as a component of polymicrobial bacteremia, with 21 to 45 percent of bloodstream isolates of *Enterococcus* being accompanied by one or more other pathogens.[53,156,205,245] As many as half of cases of catheter-related enterococcal bacteremia are polymicrobial.[163,205] Many,[97,156] but not all,[106,163] series of patients with enterococcal bacteremia have reported increased mortality rates in patients with polymicrobial bacteremia (including *Enterococcus*) versus isolated enterococcal bacteremia. Mortality in adults with nosocomial enterococcal bacteremia has ranged from 23 to 46 percent,[156,157,205] but patients at risk for the acquisition of nosocomial enterococcal bacteremia are severely ill and have a poor prognosis independent of the bacteremic event. However, hospital-acquired enterococcal infections can be life-threatening,[63,182,205,209] and specific therapy does appear to reduce the overall mortality rate.[64,107,205] Furthermore, a meta-analysis concluded that vancomycin resistance is independently correlated with increased mortality in patients with enterococcal bloodstream infections.[55,56] Nonetheless, many episodes of enterococcal bacteremia in high-risk patients apparently resolve in the absence of specific therapy.[107,269] The mortality rate associated with enterococcal bacteremia in children has been lower than that reported in adults in most studies but has ranged from 7.5 percent[53] to 12 percent[18] to 20 percent[15] to 26 percent,[41] depending on the population studied.

*References 117, 118, 252, 253, 262, 287.

In adults, many cases of enterococcal bacteremia are associated with a primary focus, most commonly a urinary tract infection.[57,91] In contrast, few children with enterococcal bacteremia have urosepsis, and most episodes of enterococcal bacteremia in children have not been associated with any identifiable focus.[18,217] However, Christie and coworkers[41] identified a primary focus in 21/57 children (37%) with nosocomial enterococcal bacteremia, including 7 patients with urosepsis and 6 with peritonitis. Many children with enterococcal bacteremia do have underlying disease involving the gastrointestinal or respiratory tract.[15,18] Central venous catheter–related enterococcal bacteremia is a significant problem in both children[15,18,41,53,58,205] and adults.[89,205] In earlier series, infections of vascular catheters were reported to account for only 2 to 14 percent of cases of enterococcal bacteremia (reviewed by Graninger and Ragette[90]), but subsequent reports have implicated intravascular devices in as many as 22 to 28 percent of these episodes in adults and children.[53,205]

Most episodes of enterococcal bacteremia do not lead to endocarditis,[156,182,205] and endocarditis is particularly uncommon in the setting of nosocomial enterococcal bacteremia. Maki and Agger[156] identified only one case of endocarditis in 118 episodes of hospital-acquired enterococcal bacteremia, whereas endocarditis was diagnosed in 12/35 patients with community-acquired enterococcal bacteremia.

Intra-abdominal Infections

Most of the published information about the role of *Enterococcus* in intra-abdominal and pelvic infections comes from series of adult patients. Enterococci commonly are isolated as components of polymicrobial infections involving the abdomen or pelvis,[88] and animal models suggest that these organisms can play a synergistic role in the pathogenesis of such infections.[115] However, evidence that the addition of specific antienterococcal therapy improves the outcome of human intra-abdominal and pelvic infections, even when enterococci are isolated from peritoneal cultures, is not compelling.[88]

Children with enterococcal bacteremia frequently have underlying conditions related to the gastrointestinal tract.[15,18,41] Bonadio[15] reported five cases of enterococcal bacteremia in previously healthy infants with gastroenteritis, six cases associated with bowel obstruction, and one case associated with acute appendicitis without perforation. Boulanger and coworkers[18] identified underlying conditions affecting the gastrointestinal system in 8/32 pediatric patients, but they were unable to specifically implicate any of these conditions as the source of the bacteremia. Das and Gray[53] detected underlying chronic gastrointestinal pathology (short-gut syndrome, congenital anomalies of the gastrointestinal tract, ulcerative colitis, chronic liver disease) in fully a third (25/75) of pediatric patients with enterococcal bacteremia.

Meningitis

Enterococci are rare causes of bacterial meningitis in adults and children. Stevenson and colleagues[256] found

only four cases of enterococcal meningitis among 493 episodes (0.8%) of bacterial meningitis in adults, and they identified an additional 90 cases in a literature search of the interval from 1966 to 1992. These authors reviewed 16 published cases of enterococcal meningitis in children: 11 of these 16 pediatric cases were complications of central nervous system (CNS) trauma or surgery, but four children (three of the four were neonates) had primary meningitis.[256] Enterococci are uncommon but well-recognized causes of infection involving cerebrospinal fluid (CSF) shunts and related devices.[113,134,188,235,286] Meningitis rarely complicates nosocomial bacteremia in adults,[156,205] but it has been reported more frequently in children (particularly neonates) with bacteremia. For example, meningitis developed in 7 percent (4/57) of episodes of nosocomial enterococcal bacteremia in children in Cincinnati[41] and in 15 percent (4/26) of premature neonates with late-onset enterococcal sepsis in Houston.[58]

Stevenson and associates[256] found that most adults with enterococcal meningitis were immunocompromised (most were receiving steroids) or had a history of CNS, surgery, or both. Enterococcal meningitis has been reported in an adult patient with HIV infection who had completed a course of steroids for presumed *Pneumocystis* pneumonia.[206] Although many children with enterococcal meningitis do have a history of CNS trauma or surgery or are premature infants, most do not have other identifiable predisposing conditions or a history of immunosuppressive therapy. As with the majority of enterococcal infections, most isolates from CSF are *E. faecalis*, but meningitis and ventriculoperitoneal shunt infections caused by *E. faecium* also have been reported in children and adults.[188,190,207]

Neonatal Infections

Enterococci are important neonatal pathogens,* and the published experience with neonatal enterococcal infections constitutes much of the pediatric experience with these organisms. Although several large series of neonatal sepsis included few cases of enterococcal infection (reviewed by Klein and Marcy[133]), many centers have reported that *Enterococcus* is a relatively frequent cause of neonatal bacteremia. Siegel and McCracken[247] found that enterococci were second only to group B streptococci as causes of neonatal sepsis at Parkland Hospital in Dallas from 1974 to 1977, with an incidence rate of approximately 1 case/1000 live births. Gladstone and colleagues[84] reported that *Enterococcus* caused 18/270 (6.7%) episodes of neonatal sepsis at Yale–New Haven Hospital during the period 1979 to 1988, which ranked fourth in incidence behind group B streptococci (64 cases, 23.7%), *Escherichia coli* (46 cases, 17.0%), and coagulase-negative staphylococci (36 cases, 13.3%). During the 1990s, reports from Houston,[58] Cincinnati,[41] and New York City[163] documented sharp increases in the rate of late-onset neonatal infection with enterococci in both hospitalized high-risk premature neonates and infants[58,163] and otherwise healthy term newborns with "community-acquired" infection.[58]

Enterococci cause both early-onset (<7 days of age) and late-onset (>7 days of age) neonatal sepsis. Early-onset disease is indistinguishable from that caused by other neonatal pathogens, but it tends to be less severe.[58] Dobson and Baker[58] identified 56 neonates with enterococcal sepsis during a 10-year period at Jefferson Davis Hospital in Houston; 18/56 (32%) had early-onset sepsis, 26/56 (46%) had late-onset sepsis, and 12/56 (21%) had sepsis associated with necrotizing enterocolitis (2 early onset, 10 late onset). In this study, 25/26 (96%) infants with late-onset enterococcal sepsis were premature infants. Christie and colleagues[41] identified 83 cases of enterococcal bacteremia between 1986 and 1992 at Children's Hospital of Cincinnati; 58 of the 83 episodes occurred in neonates. Most cases (57/83, 68.7%) were nosocomial, but many (26/83, 31.3%) were community acquired. Young infants (<3 months of age) accounted for almost all (24/26, 92.3%) of the community-acquired episodes and for many (34/57, 59.6%) of the nosocomial infections. Bonadio[15] and Boulanger and colleagues[18] also reported community-acquired enterococcal bacteremia in young infants.

McNeeley and associates[163] identified 138 episodes of enterococcal bacteremia in a New York City neonatal ICU during a 20-year period and reviewed 100 of the episodes in detail. These authors noted a sharp increase in the rate of enterococcal bacteremia during the second decade (1984 to 1994) of this study and found that most cases occurred in older infants; during this decade, the mean age at onset was 44.7 days (vs. 16.1 days during the first decade of the study), and 65 percent (51/78) of the episodes occurred after the infants reached 30 days of age. Most of the infections occurred in neonates with indwelling central venous catheters (77%), and more than half of the patients had evidence of gastrointestinal disease (necrotizing enterocolitis in 33% and abdominal distention in an additional 21%). The overall mortality rate in this study was 28 percent, although many of the deaths were not attributed to the enterococcal infection. Most (64%) of the episodes of enterococcal bacteremia in this series were polymicrobial.[163]

Nosocomial outbreaks of enterococcal infection, including VRE infection, have been reported in several neonatal units in the United States.[41,49,154,211,214] Indwelling central venous catheters, necrotizing enterocolitis, and intra-abdominal surgery are important predisposing factors for the development of nosocomial enterococcal bacteremia in neonates, whereas the genitourinary tract is implicated much less frequently as a source.[41,163]

Enterococcal bacteremia in neonates and young infants has been associated with diarrhea[15,58] and respiratory disease,[15,58] although a causative role for *Enterococcus* in the pathogenesis of gastroenteritis or pneumonia remains undefined. Enterococci rarely cause urinary tract infections in neonates,[15,41,58,163] but nosocomial and community-acquired cases have been reported. Enterococci have been noted to cause a variety of other

*References 6, 8, 31, 32, 34, 49, 64, 72, 84, 96, 99, 100, 128, 143, 154, 171, 179, 182, 183, 186, 193, 211, 216, 217, 222.

neonatal infections, including focal skin and soft tissue infections such as scalp abscess,[58] omphalitis,[58] and conjunctivitis.[273]

Most enterococcal infections in neonates are caused by *E. faecalis*, but outbreaks of infection with *E. faecium* have been reported.[49] In the series from Cincinnati reported by Christie and associates[41] and consisting largely of neonates, 82 percent of enterococcal isolates were *E. faecalis* and 14 percent were *E. faecium*. McNeeley and colleagues[163] reported the isolation of *E. faecalis* from 94/100 patients and *E. faecium* from 15/100 patients in their series (both organisms were isolated from nine of the patients). Six of the *E. faecium* isolates were resistant to vancomycin, and all six patients with VRE bacteremia died, although only one death appeared to be related directly to the VRE infection.

Septic Arthritis

Enterococci rarely have been reported to cause septic arthritis, but they can infect native or prosthetic joints. Raymond and colleagues[212] reported a case of enterococcal septic arthritis involving a prosthetic hip and reviewed an additional 18 cases from the literature. Of these 19 episodes, 11 involved prosthetic joints (2 hips, 9 knees), and 8 involved native joints; only 1 of the 8 individuals with native-joint arthritis had an underlying abnormality of the joint. In 7 of the 19 episodes, *Enterococcus* was isolated from synovial fluid, along with a second organism (3 with coagulase-negative staphylococci, 1 with group B streptococci, 1 with *Pseudomonas*, 1 with *Streptococcus*, and 1 with *Kingella kingae*). Only one pediatric case was identified: a 21-month-old girl with septic arthritis of the wrist whose joint aspirate grew *Enterococcus* spp. and *K. kingae*.[246]

DIAGNOSIS

Enterococcal infections usually are diagnosed by isolation of *Enterococcus* from a culture of blood or another normally sterile site. As discussed earlier, enterococci are ubiquitous inhabitants of the human gastrointestinal tract, and isolation of these organisms from stool or surface cultures is not evidence of invasive infection. Although enterococci are uncommon blood culture contaminants, transient bacteremia, pseudobacteremia, or both may be caused by these organisms.[107,269]

More problematic is the interpretation of a positive culture for enterococcus as a component of polymicrobial infections, particularly intra-abdominal and pelvic infections. In this setting, the role of the enterococcus in pathogenesis is unclear, and therapeutic regimens that do not include antienterococcal agents usually suffice to effect a clinical cure.[88] However, rare cases of breakthrough enterococcal bacteremia have been reported with these regimens, and one study found a decreased rate of abdominal surgical wound infections when antienterococcal coverage was provided in a prophylactic regimen.[276]

ANTIMICROBIAL SUSCEPTIBILITY AND RESISTANCE

The increasing importance of *Enterococcus* as a human pathogen, especially in the nosocomial setting,* is of particular concern because of the concomitant development of antimicrobial resistance by these organisms. Furthermore, antibiotic resistance probably has played a critical role in allowing the organism to persist and eventually cause disease in high-risk patients despite its relatively low virulence.

Some enterococci have acquired high-level resistance to all three classes of antimicrobial agents that traditionally have been used to treat life-threatening enterococcal infections—β-lactams, aminoglycosides, and glycopeptides. This acquired resistance has occurred in the context of intrinsic (usually lower level) resistance of enterococci to many antibiotics, and physicians have been confronted with the possibility that invasive disease caused by these organisms might not respond to any available antibiotics. Some enterococci also have acquired resistance to recently developed agents (e.g., linezolid, daptomycin) that are active against most antibiotic-resistant gram-positive cocci (see later discussion).

Intrinsic Resistance

β-Lactam Antibiotics

Relative resistance to β-lactam antibiotics is an intrinsic characteristic of enterococci that occurs even in human populations without previous exposure to antibiotics[172]; such resistance is due to the lower affinity of enterococcal (vs. streptococcal) penicillin-binding proteins, especially PBP-5.[171,279] In general, the minimal inhibitory concentration (MIC) of penicillin for most *E. faecalis* isolates (2 to 8 μg/mL) is at least 10 to 100 times higher than that of most streptococci, and *E. faecium* is even more resistant (MIC of 8 to 32 μg/mL or higher).[182] Ampicillin is the most active of the β-lactam antibiotics against enterococci, with average MIC values approximately twofold lower than those for penicillin.[171,172,182] Nafcillin generally is less active than penicillin, and methicillin is much less active (MIC >50 μg/mL for *E. faecalis*), as are carbenicillin and ticarcillin. Importantly, enterococci exposed to β-lactam antibiotics rapidly become tolerant of the killing effects of these agents.[171,182] Along with intrinsic resistance to these agents, tolerance limits the utility of β-lactam monotherapy for the treatment of endocarditis or other severe enterococcal infections.

Imipenem has some activity against *E. faecalis* but is much less active against *E. faecium*.[171,182] None of the cephalosporins currently approved for use in pediatrics have clinically useful activity against the enterococci, and frequent use of broad-spectrum cephalosporins and imipenem has been identified as a risk factor for the acquisition of nosocomial enterococcal infection.

*References 28, 65, 123, 163, 170, 182, 220, 284, 285.

Aminoglycosides

Enterococci are intrinsically resistant to all aminoglycosides because of diminished uptake of these drugs. For most *E. faecalis* isolates, the MIC for gentamicin or tobramycin ranges from 8 to 64 μg/mL and for streptomycin ranges from 12 to 250 μg/mL.[165,204,267] Moellering and Weinberg[173] and Zimmerman and colleagues[290] first demonstrated that the addition of a cell wall–active antibiotic results in dramatically increased aminoglycoside uptake by enterococci and that combinations of β-lactam and aminoglycoside antibiotics can lead to synergistic killing of these organisms. All *E. faecium* strains exhibit higher MICs (than does *E. faecalis*) to certain aminoglycosides, including tobramycin, netilmicin, kanamycin, and sisomicin, and these aminoglycosides do not exhibit synergy with β-lactam antibiotics against *E. faecium*.[36,182]

Other Antibiotics

Under carefully standardized laboratory conditions, enterococci are inhibited by the combination of trimethoprim and sulfamethoxazole (TMP-SMX). However, *Enterococcus* isolates should be considered resistant to TMP-SMX because these organisms are capable of using exogenous folinic acid to evade the antimicrobial action of TMP-SMX.[289] TMP-SMX fails to eradicate enterococci in animal models of infection,[33,95] and breakthrough enterococcal bacteremia has occurred in patients being treated with TMP-SMX for enterococcal urinary tract infection.[87] Enterococci also are intrinsically resistant to clindamycin, a drug with excellent activity against many other gram-positive cocci. Most enterococci have a clindamycin MIC of 12.5 to 100 μg/mL.[182] As with low-level β-lactam resistance, clindamycin resistance is found in enterococcal isolates from human populations with no previous antibiotic exposure.[172]

Acquired Resistance

Enterococci have acquired resistance to antibiotics by the acquisition of both narrow and broad host range plasmids and via the exchange of conjugative transposons (reviewed by Murray[182]). Resistance mediated by broad host range plasmids is of particular concern because glycopeptide resistance encoded by broad host range plasmids has been transferred to staphylococci in vitro[195] and in vivo.[29,30,265,275]

High-Level Resistance to Aminoglycosides

Intrinsic resistance of enterococci to aminoglycosides is caused by poor drug uptake by these organisms and can be overcome effectively both in vitro and in vivo by the addition of cell wall–active antibiotics. In contrast, high-level resistance to aminoglycosides is mediated either by the acquisition of plasmids encoding aminoglycoside-modifying enzymes (affecting all aminoglycosides via several different enzymes) or by ribosomal mutations (streptomycin only). High-level aminoglycoside resistance is of great clinical importance because it eliminates synergism between the affected aminoglycoside or aminoglycosides and β-lactam or glycopeptide antibiotics.[36,182,204] All *E. faecium* strains produce a chromosomally encoded aminoglycoside acetyltransferase that eliminates synergistic killing between cell wall–active antibiotics and certain aminoglycosides (including tobramycin, kanamycin, netilmicin, and sisomicin),[36] but it does not result in high-level resistance to these compounds. Consequently, these particular aminoglycosides should not be used to treat infections caused by *E. faecium*.

Enterococci with high-level resistance (MIC usually ≥2000 μg/mL) to streptomycin, kanamycin, and several other aminoglycosides (excluding gentamicin) were identified more than 40 years ago[174] and were widely prevalent in the United States by the mid-1970s.[24] High-level resistance to streptomycin occurs via two mechanisms, ribosomal mutation or enzymatic modification by 6′-adenylyltransferase. Initial reports of high-level resistance to kanamycin were associated with the production of 3′-phosphotransferase.[36,182]

Horodniceanu and colleagues[109] first reported high-level resistance to gentamicin in *E. faecalis* in 1979, and this resistance was shown later to be mediated by a fusion enzyme containing both 6′-acetyltransferase and 2″-phosphotransferase activity. Expression of this fusion enzyme conferred resistance to all clinically useful aminoglycosides except streptomycin.[142,143] Enterococci expressing this fusion protein usually have gentamicin MICs that are 2000 μg/mL or higher. Thus, enterococci expressing this fusion enzyme and the 6′-adenylyltransferase mediating streptomycin resistance (or chromosomally mediated streptomycin resistance) are highly resistant to all available aminoglycosides and generally fail to be killed synergistically by any combination of β-lactam antibiotics and aminoglycosides. Strains of *E. faecalis* resistant to both streptomycin and gentamicin (and thus to all aminoglycosides) were detected first in Houston, Bangkok, and Santiago in 1983.[165,182] Subsequently, strains of *E. faecalis*, *E. faecium*, and other enterococci resistant to gentamicin, streptomycin, or both (or all) aminoglycosides have become increasingly prevalent* (Table 84-2). Although high-level resistance to both streptomycin and gentamicin was described first in *E. faecalis*, it now is at least as common in *E. faecium*.[121]

Enterococci resistant to all aminoglycosides frequently have been isolated from clinical specimens for the past 2 decades. Jones and colleagues and the *Enterococcus* Study Group[120] found that fully 20 percent of 1936 enterococcal isolates from late 1992 (from 97 participating laboratories in 47 states) exhibited high-level resistance to both gentamicin and streptomycin. Low and associates and the SENTRY Antimicrobial Resistance Surveillance Program[153] reported similar rates of high-level resistance to both gentamicin and streptomycin from 1997 to 1999 (see Table 84-2). Almost a third (32.8%) of enterococci collected by the SENTRY group from 1997 to 2005 were highly resistant to gentamicin.[122] Many medical centers in the United States now report that most enterococcal isolates exhibit high-level resistance to all aminoglycosides.[186]

*However, 11/632 (1.7%) *E. faecalis* isolates were β-lactamase producers.
†No β-lactamase–producing strains were identified.
‡Only two β-lactamase–producing isolates were identified.

Several new aminoglycoside-resistant genes were identified in enterococci during the late 1990s (reviewed by Chow[36]). Some enterococci produce three or more enzymes. Strains expressing some of the recently described resistant genes may fail to exhibit synergy between gentamicin and β-lactams despite MICs below those usually associated with high-level resistance. For example, the *aph (2″)-Ic* gene[39] found in clinical isolates of both *E. faecalis* and *E. faecium* results in gentamicin MICs of approximately 256 to 384 μg/mL, lower than the standard screening cutoff for high-level resistance to gentamicin (500 μg/mL). Nonetheless, these organisms are resistant to ampicillin-gentamicin synergism and would not be detected by standard screening methods.

High-Level Resistance to β-Lactams and Production of β-Lactamase

The mechanisms of resistance to penicillin, ampicillin, and other β-lactam antibiotics differ among enterococcal species. High-level β-lactam resistance (ampicillin MIC ≥16 μg/mL) of *E. faecium*[20,94,161] and some other non-*faecalis* enterococcal strains[20] is now common and is mediated by additional alterations in penicillin-binding proteins (PBPs), particularly PBP-5.[76,94,219] Thus, high-level resistance to ampicillin and other β-lactams in *E. faecium* (and other non-*faecalis* strains) represents an exaggerated form of intrinsic β-lactam resistance. *E. faecalis* isolates also are intrinsically resistant to β-lactams (though less so than *E. faecium*), but little change has occurred in the level of this resistance in recent years. However, some strains of *E. faecalis*[121,183,187] and *E. faecium*[48] have acquired clinically significant resistance to ampicillin and penicillin via the plasmid-mediated, constitutive production of a β-lactamase enzyme identical to that of *S. aureus*.[291] β-Lactamase–producing strains of *E. faecalis* and *E. faecium* will not be detected by routine susceptibility testing because of a pronounced inoculum effect. Therefore, enzymatic methods such as the nitrocefin test must be used to screen for β-lactamase–producing strains.[129,183] Fortunately, such strains remain very uncommon.[4,171]

Glycopeptide Resistance

Enterococci resistant to vancomycin were identified first in 1988[140,270] and rapidly have become a major nosocomial problem. Data collected by the CDC NNIS revealed a dramatic increase in the rate of vancomycin resistance in nosocomial isolates of *Enterococcus* during the interval 1989 to 1993.[28] The NNIS survey documented a 26-fold increase in vancomycin resistance among all nosocomial isolates (from 0.3% of enterococcal isolates in 1989 to 7.9% in 1993) and a 34-fold increase in vancomycin resistance among isolates obtained from adult patients in ICUs (from 0.4% of isolates in 1989 to 13.6% in 1993). Rates of vancomycin resistance in enterococci continued to increase during the next decade (see Table 84-2). The NNIS reported that fully 25 percent of enterococci associated with nosocomial infections in adult patients in ICUs in the United States were resistant to vancomycin in 1999 and 2000; by 2003 to 2004, approximately 30 percent of the enterococcal isolates from these patients were vancomycin-resistant.* Isolates of *E. faecium* are particularly likely to be vancomycin-resistant. Jones and colleagues[122] in the SENTRY Antimicrobial Resistance Surveillance Program reported that 69.4 percent of 1512 U.S. bloodstream isolates of *E. faecium* collected between 1997 and 2005 were resistant to vancomycin. Similarly, Wisplinghoff and colleagues[284] in the SCOPE surveillance study found that 60 percent of U.S. bloodstream isolates of *E. faecium* collected between 1995 and 2002 were resistant to vancomycin, whereas only 3 percent of *E. faecalis* bloodstream isolates were vancomycin-resistant.

Enterococci were the second most common organisms associated with pediatric bloodstream infections in both the 1992 to 1997 NNIS database[222] and the pediatric component of the 1995 to 2001 SCOPE survey.[284] However, VRE organisms were detected much less frequently in these pediatric patients; only 11 percent of *E. faecium* and 1 percent of *E. faecalis* bloodstream isolates (of 357 total enterococcal isolates) obtained from pediatric patients in the SCOPE study were vancomycin-resistant.[284] This finding is important because vancomycin-resistant isolates, particularly those of *E. faecium*, also may exhibit high-level resistance to both β-lactam antibiotics and aminoglycosides, thus rendering treatment of these infections extremely challenging.†

Vancomycin resistance among enterococci is phenotypically and genotypically heterogeneous[6,85,185,186] and may or may not be associated with resistance to other glycopeptides, including teicoplanin. Five major phenotypes of vancomycin resistance (VanA, VanB, VanC, VanD, and VanE) have been characterized. The VanA and VanB phenotypes are most common, and both are transferable. The VanA phenotype is characterized by high-level resistance to vancomycin and teicoplanin, whereas strains with the VanB phenotype exhibit variable levels of resistance to vancomycin but not teicoplanin.[6,85,185,186] The VanC phenotype is limited to *E. gallinarum* and *Enterococcus casseliflavus* and is associated with constitutive, low-level, chromosomally mediated (nontransferable) resistance to vancomycin but not teicoplanin.[85,185,186,217] VanD and VanE phenotypes occur uncommonly and are not transferable.

High-level resistance to both vancomycin and teicoplanin (the VanA phenotype) is found primarily in strains of *E. faecium*, whereas most vancomycin-resistant strains of *E. faecalis* express the VanB phenotype and remain susceptible to teicoplanin. Jones and associates and the *Enterococcus* Study Group found that 10/11 (91%) vancomycin-resistant strains of *E. faecalis* remained susceptible to teicoplanin (VanB phenotype), whereas 49/62 (79%) vancomycin-resistant strains of *E. faecium* were resistant to teicoplanin (VanA phenotype).[121]

The biochemical mechanisms responsible for the major vancomycin-resistant phenotypes are the subject of intense study (reviewed by Murray[184] and Gold[85]). Both

*See CDC website: http://www.cdc.gov/ncidod/dhqp/pdf/ar/ICU_RESTrend1995-2004.pdf.

†References 19, 81, 100, 124, 145, 177-179, 216, 217, 222, 241, 242.

VanA and VanB phenotypes are mediated by homologous enzymes that catalyze the formation of an altered, vancomycin-resistant depsipeptide that is incorporated into cell wall peptidoglycan.[6,186,217] The *vanA* and *vanB* gene clusters share functional similarities but are regulated quite differently.[85,186] VanA resistance is transferable by either a transposon or conjugative plasmids. VanB resistance often is encoded by chromosomal DNA but may be transferred by at least two different transposons.[85,186] Vancomycin induces the production of enzymes encoded by both the *vanA* and *vanB* gene clusters, whereas teicoplanin induces VanA but not VanB enzymes.[85]

Resistance to Other Antibiotics

Recently licensed antimicrobials active against most antibiotic-resistant, gram-positive cocci (including VRE organisms) include linezolid and daptomycin. The minocycline derivative tigecycline also is active against most enterococci but has not been well studied for the treatment of these infections. Finally, another agent, the streptogramin quinupristin-dalfopristin, is active against *E. faecium* but not *E. faecalis* isolates and because of this limitation and its considerable toxicity has little utility in pediatrics.

The oxazolidinones are a novel class of synthetic protein synthesis inhibitors that act to inhibit the formation of ribosomal initiation complexes in bacteria.[43] Linezolid, the first oxazolidinone antimicrobial approved for human use, is active against both *E. faecalis* and *E. faecium*, including most VRE isolates. Initial studies demonstrated virtually uniform activity of this agent against clinical isolates of enterococci,[17,67,198] with 100 percent of 180 strains (representing multiple resistance profiles) inhibited by linezolid concentrations of 1 to 4 μg/mL in one study.[67] Furthermore, initial in vitro studies suggested that the development of resistance would occur very rarely.[43,123,292] However, resistance to linezolid has been reported in several patients receiving prolonged courses of therapy with this drug[4,86,159,167,238] and in some patients who have not previously received the agent,[16] and it has been associated with clinical failures.[4,86] Resistance to linezolid is conferred by single nucleotide changes in varying numbers of copies of the bacterial genes encoding 23S ribosomal RNA.[167] Resistance increases in strains containing multiple copies of these mutations.[158,167] Although some centers have reported increasing rates of linezolid resistance in VRE isolates[167] and nosocomial spread of linezolid-resistant VRE strains,[105] overall rates of linezolid resistance in enterococci remain low. For example, only 0.9 percent of 1512 U.S. bloodstream isolates of *E. faecium* collected from 1997 to 2005 by the SENTRY group were resistant to linezolid[122] and only 0.75 percent of 934 enterococcal isolates studied in 2010 as part of the LEADER surveillance program were resistant to linezolid.[74]

Daptomycin is a novel cyclic lipopeptide antimicrobial that exhibits rapid, concentration-dependent bactericidal activity against gram-positive pathogens, including methicillin-resistant *Staphylococcus aureus* (MRSA) and VRE strains.[27,254] Daptomycin has a novel method of action in which binding to bacterial membranes and triggering of rapid depolarization of membrane potential lead to inhibition of protein and nucleic acid synthesis.[81] Daptomycin was found to have potent activity against a panel of VRE isolates from the United States and Europe—all 75 VRE isolates tested (i.e., 55 *E. faecium* and 20 *E. faecalis*) were susceptible to this agent.[226] Daptomycin also was reported to be active against a collection of VRE strains resistant to linezolid or quinupristin-dalfopristin.[2] However, daptomycin resistance has developed during therapy with this agent,[148,181,224] although resistance rates remain very low. Sader and colleagues[225] studied 4312 *E. faecalis* isolates (195 VRE) and 2462 *E. faecium* isolates (1867 VRE) collected between 2005 and 2010; 99.98 percent of the *E. faecalis* isolates and 99.68 percent of the *E. faecium* isolates were susceptible to daptomycin. The mechanisms responsible for daptomycin resistance are poorly understood.

Streptogramins are protein synthesis inhibitor antibiotics and are natural combinations of two chemically unrelated molecules, streptogramin A and B.[151] Quinupristin-dalfopristin is a streptogramin agent that is active against *E. faecium* (including most strains of VREF) but lacks activity against *E. faecalis* at clinically achievable concentrations.[47] An early study found that more than 95 percent of 875 initial patient isolates of VREF were susceptible to quinupristin-dalfopristin,[68] but both emergence of resistance to this agent[175,226] and superinfection with *E. faecalis* and other organisms[37,283] have been reported during therapy with this drug. In the United States, overall rates of enterococcal resistance to quinupristin-dalfopristin remain low, in the range of 1 to 2 percent in most areas.[106]

Testing for Antimicrobial Resistance in Enterococci

All enterococci isolated from cultures of blood, CSF, or other normally sterile sites (with the possible exception of urine) should be tested for resistance to β-lactam antibiotics (i.e., ampicillin, penicillin, or both, including a test for β-lactamase production), vancomycin, and high levels of aminoglycosides (streptomycin and gentamicin)[70,212,217] by using the methodology and interpretative guidelines published by the Clinical and Laboratory Standards Institute (CLSI).[44] For multiantibiotic-resistant isolates, testing for susceptibility to alternative agents, including linezolid and daptomycin, should be performed.

Testing of enterococci for ampicillin (or penicillin) resistance must involve determination of the MIC of these agents and a test for β-lactamase production.[44] Jones and colleagues[120] and the *Enterococcus* Study Group compared three techniques that are used commonly to determine the ampicillin MIC of enterococcal isolates—disk diffusion, broth microdilution, and E-test strips—and found excellent agreement among the three methods. Enterococcal isolates with an ampicillin or penicillin MIC of 16 μg/mL or greater are considered resistant to these agents.[44] β-Lactamase–producing enterococci cannot be detected by these methods but are identified routinely by performance of the chromogenic nitrocefin assay.[258]

High-level resistance to gentamicin and streptomycin usually may be detected by either agar dilution (high-level resistance to gentamicin, MIC >500 μg/mL; high-level resistance to streptomycin, MIC >2000 μg/mL) or broth microdilution (high-level resistance to gentamicin, MIC >500 μg/mL; high-level resistance to streptomycin, MIC >1000 μg/mL).[44,258,259] These isolates also may be identified by disk diffusion with the use of high-content aminoglycoside disks (120-μg gentamicin disk, 300-μg streptomycin disks, ≥10-mm zone = susceptible)[259] or high-range E-test strips.[120,230] However, the recent identification of novel genes encoding gentamicin resistance in both *E. faecalis* and *E. faecium* has raised concern about continued use of the 500-μg/mL cutoff for detection of high-level resistance to gentamicin (reviewed by Chow[36]). These enterococcal isolates are not killed synergistically by combinations of ampicillin or penicillin and gentamicin, even though gentamicin MICs are 256 to 384 μg/mL. If these isolates become more widely prevalent, modification of the standard screening procedures for high-level aminoglycoside resistance may be required.

Commercially available automated antimicrobial susceptibility testing methods may fail to detect vancomycin resistance in enterococci, particularly the VanB phenotype of moderate resistance,[264] although newer versions of these systems appear to be much more reliable.[83,271] Routine disk diffusion testing is more dependable but requires an extended incubation time and the use of transmitted light for examination of zone size to be highly accurate.[260,264] Agar dilution screening using brain-heart infusion agar supplemented with 6 μg/mL vancomycin reliably identifies VRE strains,[44,258,277] as does the standard broth microdilution method.[121,264] E-test glycopeptide strips are a useful alternative to the more cumbersome broth dilution methodology.

THERAPY FOR ENTEROCOCCAL INFECTIONS

Before the emergence of VRE infection as a major nosocomial problem in high-risk patients, the optimal management of serious enterococcal infections (especially endocarditis) was well established. Successful treatment of enterococcal endocarditis required the administration of combination therapy consisting of a cell wall–active agent (usually ampicillin) and an aminoglycoside (gentamicin or streptomycin). Combination therapy also was recommended for other potentially life-threatening enterococcal infections (e.g., sepsis or meningitis) based on the extensive experience with endocarditis. Other enterococcal infections, including urinary tract infections, responded well to monotherapy with a variety of antimicrobials.

In contrast, the optimal therapy for many infections caused by VRE strains remains uncertain. Both linezolid and daptomycin have now been used extensively for the treatment of VRE infections in adults. However, only one of these antibiotics (linezolid) has been approved for use in children, and enterococci resistant to these new agents already have been detected.[167,181]

Treatment of Infections Caused by Antibiotic-Susceptible Enterococci

Any discussion of the treatment of serious enterococcal infection must begin with a review of the large experience in the treatment of enterococcal endocarditis. The difficulty of treating enterococcal endocarditis has been apparent since early reports showed that penicillin alone failed to cure as many as two thirds of patients with enterococcal endocarditis but was highly effective in the treatment of streptococcal endocarditis (reviewed by Murray[182]). The early failures of penicillin therapy stimulated studies of the in vitro and in vivo effects of β-lactam antibiotics on enterococci. These studies led to the discovery that enterococci were "tolerant" of the killing effects of cell wall–active agents and provided evidence that bactericidal therapy was required to cure bacterial endocarditis reliably.

For more than 65 years, standard therapy for enterococcal endocarditis has included an aminoglycoside plus a cell wall–active agent. Hunter[111] first reported clinical evidence of synergism between penicillin and streptomycin in the treatment of enterococcal endocarditis in 1947, and this synergism subsequently was confirmed for combinations of penicillin or ampicillin and streptomycin or gentamicin, both in vitro and in vivo (reviewed by Murray[182]). Moellering and Weinberg[173] first demonstrated that synergy between β-lactams and aminoglycosides was a consequence of increased aminoglycoside uptake by enterococci exposed to cell wall–active agents. Glycopeptides and aminoglycosides also exhibit in vitro and in vivo synergy against "susceptible" (not expressing high-level resistance) strains of enterococci.[108,171]

The preferred therapy for endocarditis caused by "susceptible" strains of enterococci in both adults* and children[52,253] consists of combination therapy with parenteral ampicillin (or penicillin G) plus parenteral gentamicin (or streptomycin) for a minimal duration of 4 to 6 weeks. Patients with severe penicillin allergy should be treated with vancomycin plus gentamicin or streptomycin. Selected adult patients with a short duration of symptoms and an uncomplicated course may be treated with 4-week regimens[280]; most other patients, including those with mitral valve involvement, a longer duration of symptoms (especially those with symptoms for >3 months), or prosthetic valve endocarditis, probably should receive 6-week courses of therapy.[166,280] Interestingly, several reports indicate that the prognosis of enterococcal prosthetic valve endocarditis is better than that of native valve disease, perhaps because of the generally shorter duration of symptoms before the diagnosis is made.[166,218] Many patients with prosthetic valve endocarditis caused by enterococci can be cured without surgery. Rice and colleagues[218] reported a 69 percent cure rate with medical therapy in patients with enterococcal endocarditis involving prosthetic valves.

The general consensus, based on experience with enterococcal endocarditis, is that other life-threatening enterococcal infections, including meningitis and septicemia,

*References 4, 14, 166, 171, 218, 280.

should be treated with bactericidal regimens.[170,182,256] The duration of therapy for uncommon enterococcal infections such as meningitis must be individualized, although 2- to 3-week courses of antibiotics have been reported to cure enterococcal meningitis.[256] The optimal treatment of enterococcal bacteremia, particularly that occurring in the nosocomial setting, remains controversial.

The prognosis for these patients varies widely and often is related more closely to the underlying disease than to the enterococcal infection. In adults, single-drug regimens generally are successful in the treatment of enterococcal bacteremia, thus indicating that bactericidal therapy is not required in all cases.[170,182]

Considerable clinical experience supports the routine use of single-drug therapy for uncomplicated enterococcal urinary tract infection and for soft tissue infection caused by enterococci. Urinary tract infections by susceptible strains of enterococci generally respond promptly to ampicillin, penicillin, nitrofurantoin, or vancomycin.[170,171,180,182]

Treatment of Infections Caused by Antibiotic-Resistant Enterococci (Including Vancomycin-Resistant Enterococci)

Unfortunately, the emergence of enterococci with clinically significant resistance to aminoglycosides, β-lactams, and glycopeptides has greatly complicated the management of endocarditis and other serious infections caused by these organisms. This discussion focuses on the management of endocarditis caused by drug-resistant enterococci because the need to provide bactericidal therapy has been well established in this setting. The general principles probably apply to the management of other life-threatening enterococcal infections (see earlier discussion).

Endocarditis caused by enterococci with high-level resistance to either streptomycin or gentamicin may be treated by substituting the other aminoglycoside in a combination regimen, but isolation of strains with high-level resistance to both aminoglycosides means that no available aminoglycoside will provide synergistic killing in concert with cell wall–active agents.[166,182,281] No reliably bactericidal regimen is available for the treatment of endocarditis caused by these strains, even if the isolates remain susceptible to other classes of antimicrobials. Based on animal studies, some experts recommend prolonged treatment (≥8 to 12 weeks) with high-dose intravenous ampicillin given by continuous infusion in this situation (if the isolate is susceptible).[66,171] Surgical excision of infected valves may be required in such patients.[218]

Endocarditis and other serious infections caused by enterococci resistant to β-lactam antibiotics also are increasing in frequency.[94] Endocarditis caused by enterococci (usually *E. faecium*) highly resistant to β-lactams may be treated with vancomycin plus an aminoglycoside (if the strain is susceptible to vancomycin). Endocarditis caused by β-lactamase–producing strains of *E. faecalis* (or, rarely, *E. faecium*) would be expected to respond to ampicillin-sulbactam because this combination is highly effective in animal models.[66] Higher-dose or continuous-infusion ampicillin may be effective in the treatment of endocarditis caused by some strains of enterococci that are "resistant" to ampicillin by current guidelines (MIC ≥16 μg/mL) because sustained plasma concentrations in excess of 100 μg/mL may be achieved with these regimens.[186] However, even high-dose ampicillin therapy probably will fail to cure endocarditis caused by enterococci with ampicillin MICs greater than 64 μg/mL.[22,85]

Enterococci resistant to vancomycin may remain susceptible to teicoplanin (VanB phenotype). Teicoplanin with or without the addition of an aminoglycoside has been used successfully in the treatment of serious enterococcal infections caused by susceptible isolates,[234] including some cases of endocarditis[209,234] and meningitis.[150] However, teicoplanin is not available in the United States, treatment of endocarditis with this agent has been associated with both treatment failure and relapse,[209,234] and high-level teicoplanin resistance may develop even without exposure to the drug.[102] Endocarditis caused by VanB strains of enterococci should be treated with high-dose ampicillin plus gentamicin or streptomycin if resistance to these agents is not present.

Similarly, endocarditis caused by enterococci highly resistant to both vancomycin and teicoplanin (VanA phenotype) but susceptible to β-lactams should be treated with ampicillin plus an aminoglycoside (if high-level resistance to aminoglycosides is not present). Unfortunately, the VanA phenotype is associated primarily with strains of *E. faecium*, which increasingly are resistant to β-lactams.[76,94,120] Endocarditis caused by enterococci highly resistant to both glycopeptides and β-lactams is especially difficult to treat. Combinations of ampicillin and vancomycin are not bactericidal against these isolates but may[244] or may not[31] provide additive or synergistic inhibition in vitro. If high-level resistance to aminoglycosides is not present, triple-combination therapy with a β-lactam, a glycopeptide, and an aminoglycoside may achieve bactericidal activity; such combinations are reported to be highly effective in animal models of endocarditis caused by ampicillin- and vancomycin-resistant *E. faecium*.[26] For endocarditis caused by enterococci exhibiting high-level resistance to both gentamicin and streptomycin along with resistance to β-lactams and glycopeptides, no proven effective therapies are available.

Newer Options for Treatment of Vancomycin-Resistant Enterococcal Infections

Four new antimicrobials with activity against most VRE strains recently have been licensed: linezolid, daptomycin, tigecycline, and quinupristin-dalfopristin. Of these drugs, only linezolid has been approved for use in children.

Linezolid, the first oxazolidinone antibiotic, was approved by the U.S. Food and Drug Administration (FDA) in April 2000 for the treatment of selected infections caused by antibiotic-resistant, gram-positive bacteria in adults, including those caused by VRE strains (*E. faecium* or *E. faecalis*). In December 2002, the FDA approved this agent for treatment of pediatric patients with pneumonia, skin and skin structure infections,

and VREF infections. Linezolid is available in both parenteral and oral formulations (with comparable bioavailability). Linezolid is active against many antibiotic-resistant, gram-positive pathogens, including MRSA, penicillin-resistant *S. pneumoniae*, and vancomycin-resistant isolates of both *E. faecium* and *E. faecalis*.[17,43,67,74,198] This agent is bacteriostatic against most susceptible organisms, including the enterococci, but it does exhibit bactericidal activity against some strains of pneumococci. Initial studies demonstrated virtually uniform activity of linezolid against clinical isolates of enterococci.[17,66,199]

Linezolid has been reported to effect both bacteriologic and clinical cure in patients with life-threatening VRE infections, including endocarditis,[9,13,35,254] bacteremia,[35,164,199] and meningitis,[240,286,288] although clinical experience with this agent in the treatment of endocarditis or meningitis remains limited. Linezolid therapy has been reported to cure several patients with VRE endocarditis,[9,13,34,255] including 10/22 patients in one study[13] and all of 3 patients who received at least 6 weeks of the drug in another report.[255] These results are encouraging, but enthusiasm for the use of linezolid to treat serious VRE infection must be tempered by its generally bacteriostatic activity and the potential for increasing resistance to this agent. Some experts suggest caution in using linezolid for treatment of VRE endocarditis because of reported therapeutic failures, toxicity, and potential for emergence of resistance.[4,221] Pediatric experience with linezolid is limited, but the drug was demonstrated to be well tolerated and as effective as vancomycin in the treatment of children with serious gram-positive infections in a large multicenter trial.[125]

Linezolid generally has been tolerated well in both adults and children.[42,80,229] Adverse effects most frequently reported in patients receiving linezolid have included nausea, diarrhea, and headache in adults and diarrhea and vomiting in children.[80] Reversible myelosuppression has been reported in adults.[80] Longer courses of linezolid therapy have been associated with more serious adverse effects, including optic neuropathy that usually is reversible and peripheral neuropathy that may be irreversible.[114,223] Enterococcal resistance to linezolid remains very uncommon,[74] but has been associated with clinical failures in both adults and children.

Daptomycin is a novel cyclic lipopeptide antimicrobial that exhibits rapid, concentration-dependent bactericidal activity against enterococci, including VRE strains.[27,254] It was approved by the FDA in September 2003 for the treatment of adult patients with complicated skin and soft tissue infections caused by gram-positive bacteria, including staphylococci, streptococci, and vancomycin-susceptible strains of *E. faecalis*. Daptomycin is available in an intravenous formulation. It is not approved for use in children, and pediatric experience with the drug is limited. Daptomycin should not be used for the treatment of pneumonia because it is inactivated by pulmonary surfactant.[248]

Considerable published experience exists now with daptomycin therapy (alone and in combination with other agents) in adult patients with VRE bloodstream infections, though pediatric data remain limited. Half (11/22) of the adult patients with VRE bacteremia or endocarditis treated with daptomycin summarized in three early reports were cured.[139,208,239] Subsequently, anecdotal reports have been published documenting successful treatment of VRE bacteremia or endocarditis with daptomycin alone or in combination with other agents.[4] Higher doses of daptomycin (e.g., 8 mg/kg/day in adults) may be more effective for the treatment of bacteremia caused by VRE (and other bacteria). Limited, retrospective comparisons have failed to identify significant differences in the outcomes of VRE bacteremia treated with daptomycin or linezolid.[51,268] The published pediatric experience is limited, and clinical trials in children are under way.

Daptomycin resistance remains uncommon among enterococci[225] but may develop during therapy. Patients being treated with daptomycin should be monitored for the development of muscle toxicity by serial measurement of serum creatine kinase concentrations and screening for muscle pain or weakness.

The streptogramin antibiotic quinupristin-dalfopristin[151] was approved by the FDA in September 1999 for the treatment of adults with infections caused by VREF. This agent is not approved for the treatment of *E. faecalis* infections, nor for pediatric use. Quinupristin-dalfopristin has been reported to effect clinical cures of several serious infections caused by multiresistant *E. faecium*, including ventriculoperitoneal shunt infections in two patients,[188,268] an infected aortic graft in one patient,[228] and VREF peritonitis in a series of adults.[155] Clinical response to quinupristin-dalfopristin has been reported in approximately 74 to 80 percent of patients with VREF bacteremia.* The lack of a consistent bactericidal effect may limit the utility of this agent in the treatment of endocarditis and other life-threatening infections. Quinupristin-dalfopristin therapy generally has been tolerated fairly well in both adults and children, although a high rate of venous phlebitis in recipients has led to a recommendation that the agent be administered through a central venous catheter. Myalgias and arthralgias are other commonly reported side effects of this agent. The potential utility of quinupristin-dalfopristin for the treatment of pediatric patients is limited by its venous toxicity, its lack of a consistent bactericidal effect against VREF, and its lack of clinically useful activity against *E. faecalis*.[47]

Tigecycline is a novel glycylcycline antibiotic derived from minocycline. It is FDA approved in adults for treatment of complicated skin and soft tissue infections and abdominal infections caused by susceptible bacteria, including vancomycin-susceptible *E. faecalis*. It is active in vitro against both vancomycin-susceptible and vancomycin-resistant *E. faecalis* and *E. faecium*, but the clinical experience with this agent for treatment of VRE infections is limited and mostly consists of case reports involving combination antimicrobial therapy.[4,25] Pediatric experience is even more limited.[113]

Several other promising new antibiotics with in vitro activity against VRE isolates are being studied in clinical trials, including the lipoglycopeptides oritavancin and

*References 82, 92, 144, 146, 160, 175, 272, 283.

telavancin,[168] as well as new members of the oxazolidinone and streptogramin classes of antibiotics.

PREVENTION OF ENTEROCOCCAL INFECTIONS

The explosive increase in nosocomial infections caused by vancomycin-resistant and multiantibiotic-resistant enterococci[28,64] has rendered prevention of enterococcal infections, particularly those caused by VRE strains, a public health priority in the United States.[32,85,186,213,241] In 1995, the Hospital Infection Control Practices Advisory Committee (HICPAC) recommended a series of overlapping strategies designed to prevent the development of serious VRE infections.[213] These strategies remain useful today and are designed to simultaneously reduce vancomycin resistance in enterococci and prevent nosocomial infections caused by these organisms. Implementation of such strategies has been reported to reduce or eliminate the transmission of VRE organisms in health care facilities.[201] However, overall rates of nosocomial infection by VRE continued to increase in the United States from 1995 to 2004,* perhaps because the HICPAC guidelines were followed inconsistently (reviewed by Cetinkaya and colleagues[32]).

Reversing the Trend Toward Vancomycin and Multiple-Antibiotic Resistance in Enterococci

The use of vancomycin[213,241] and treatment with broad-spectrum antibiotics, including the third-generation cephalosporins and carbapenems,† are risk factors for colonization and the development of infection with VRE strains. Consequently, the HICPAC and CDC recommend that all hospitals, even those at which VRE organisms have not been isolated, should (1) develop a comprehensive antimicrobial utilization plan, (2) oversee surgical prophylaxis, and (3) develop institution-specific guidelines for the proper use of vancomycin.[213] These strategies are echoed in the recommendations for development of antimicrobial stewardship programs that have been made jointly by the Society for Healthcare Epidemiology of America, the Infectious Diseases Society of America, and the Pediatric Infectious Diseases Society.[251]

Efforts to eliminate unnecessary use of vancomycin are of critical importance[213,241] but may be inadequate unless the use of other classes of antimicrobials is reduced as well (see later discussion). In 1995, HICPAC provided recommendations regarding the acceptable and appropriate use of vancomycin (Table 84-3), as well as recommendations regarding situations in which vancomycin use should be discouraged[213] (Table 84-4). These recommendations remain useful, but the recent emergence of community-acquired MRSA infections[104,110,126] has resulted in increased empirical and definitive use of vancomycin for an HICPAC-approved indication: "treatment of serious infections caused by β-lactam–resistant, gram-positive microorganisms."[213]

TABLE 84-3 Situations in Which Vancomycin Use Is Appropriate or Acceptable

Treatment
Treatment of serious infections caused by β-lactam–resistant, gram-positive microorganisms
Treatment of gram-positive infections in patients with serious allergies to β-lactams
Treatment of antibiotic-associated colitis only when it fails to respond to metronidazole or is severe and potentially life-threatening
Prophylaxis
Endocarditis prophylaxis after certain procedures in high-risk patients according to the American Heart Association guidelines
Prophylaxis for major surgical procedures involving implantation of prosthetic materials or devices (single-dose prophylaxis usually is adequate)

Modified from Recommendations for preventing the spread of vancomycin resistance: Recommendations of the Hospital Infection Control Practices Advisory Committee (HICPAC). MMWR Recomm Rep 1995;**44**(RR-12):1-13.

TABLE 84-4 Situations in Which Vancomycin Use Should Be Discouraged

Treatment
Empiric therapy for febrile neutropenic patients (unless there is presumptive evidence of an infection caused by gram-positive organisms, such as a Hickman catheter exit-site infection, and the local prevalence of methicillin-resistant *Staphylococcus aureus* strains is substantial)
Treatment of an isolated, single blood culture positive for coagulase-negative *Staphylococcus*
Treatment (chosen for dosing convenience) of infections caused by β-lactam–susceptible, gram-positive microorganisms in patients with renal failure
Continued empirical use of presumed infection in patients whose cultures are negative for β-lactam–resistant gram-positive microorganisms
Primary treatment of antibiotic-associated diarrhea
Eradication of methicillin-resistant *S. aureus* colonization
Prophylaxis
Routine surgical prophylaxis except in patients with life-threatening allergy to β-lactams
Systemic or local prophylaxis for infection of indwelling intravascular catheters
Routine prophylaxis for infants with very low birth weight
Routine prophylaxis for dialysis patients
Use of vancomycin solution for topical application or irrigation
Selective decontamination of the gastrointestinal tract

Modified from Recommendations for preventing the spread of vancomycin resistance: Recommendations of the Hospital Infection Control Practices Advisory Committee (HICPAC). MMWR Recomm Rep 1995;**44**(RR-12):1-13.

†References 64, 93, 162, 179, 184, 192, 216.

In addition, efforts should be undertaken to reduce the unnecessary use of broad-spectrum antibiotics and certain agents with potent antianaerobic activity, particularly in settings with high rates of nosocomial infection (such as ICUs). These efforts are necessary because many studies indicate that nonglycopeptide antibiotics also exert selective pressure for VRE strains and that limitation of the use of vancomycin alone has only a modest effect on reducing VRE colonization and infection (reviewed by Rice[216]). Exposure to agents with broad-spectrum activity (but lacking antienterococcal activity), such as the extended-spectrum cephalosporins, appears to predispose to colonization with VRE organisms,[61,216] whereas exposure to antimicrobials with potent antianaerobic activity (even if they are also active against enterococci) may promote high-density, prolonged VRE colonization (by eliminating gut anaerobes that may interfere with colonization by VRE strains).[60,210,216]

Preventing and Controlling the Spread of Nosocomial Infection by Vancomycin-Resistant Enterococci

The increasing prevalence of *Enterococcus* in nosocomial infections is related to the intrinsic and acquired antimicrobial resistance of these organisms, but the factors leading to increased antibiotic resistance in enterococci are not identical to those that predispose to enterococcal colonization, infection, or both. Enterococcal infections are concentrated increasingly in debilitated and immunocompromised patients, including those with malignancies, recipients of bone marrow and solid organ transplants, burn victims, premature neonates, and critically ill patients with indwelling intravascular catheters. Consequently, special attention should be paid to potential outbreaks of VRE infection in hospital wards caring for these high-risk patients.[32]

Efforts to prevent the spread of VRE colonization, infection, or both probably will be more successful if the VRE isolates are confined to a few patients in a single area of the hospital (Table 84-5). Widespread colonization with VRE strains may precede identification of infections by these organisms. Therefore, all hospitals should implement active VRE surveillance and formulate a multidisciplinary plan to prevent nosocomial spread of VRE strains if such organisms are identified. In hospitals that have not isolated VRE strains, periodic antimicrobial susceptibility testing should be performed on enterococcal isolates from all sources, particularly from high-risk patient populations such as those in intensive care or transplant units. If VRE organisms are identified, a comprehensive plan to prevent nosocomial spread of these bacteria should be instituted immediately. The HICPAC guidelines summarized the essential elements of such a plan.[213] Hospital infection control staff and clinical staff must be notified promptly when VRE strains are isolated from a clinical sample, and isolation precautions should be implemented immediately to prevent patient-to-patient transmission of VRE organisms. These precautions include gown and glove isolation, vigorous hand washing, dedicated use of noncritical patient items such as thermometers and stethoscopes, and prompt surveillance of any possibly exposed patients for VRE colonization. Additional measures may be necessary in hospitals with endemic or continued VRE transmission despite implementation of the aforementioned measures.[213] Ostrowsky and colleagues[201] reported that an active infection control program that included surveillance cultures and prompt isolation of infected patients successfully reduced the spread of VRE strains in health care facilities throughout the Sioux land region of Iowa, Nebraska, and South Dakota.

Once VRE organisms become endemic in a hospital unit, achieving complete eradication is very difficult. The duration of VRE colonization in individual patients may be weeks or months,[32,177] although spontaneous resolution of colonization occurs frequently.[32,176] Attempts to eradicate colonization in individual patients generally have been unsuccessful.[32,176] Consequently, the measures recommended by HICPAC and others are directed at preventing the initial establishment of VRE strains in hospitals. Implementation of these policies will require the involvement of hospital pharmacy and therapeutics committees, quality assurance programs, and medical staff. Ongoing monitoring of the efficacy of these programs is necessary.

VIRIDANS STREPTOCOCCAL INFECTIONS

The group of *Streptococcus* species characterized as viridans, alpha-hemolytic, or oral streptococci is ubiquitously present on the human oral mucosa. These organisms are important pathogens in children and adults alike; they cause infections ranging from caries and bacterial endocarditis in immunocompetent hosts to fatal sepsis in neutropenic persons.

None of the terms applied to this group is entirely satisfactory. Not all members of the alpha-hemolytic streptococci are alpha-hemolytic, some being gamma-hemolytic (nonhemolytic) or even beta-hemolytic. Further, *Streptococcus pneumoniae*, which is alpha-hemolytic, is not considered a member of the viridans group. The term "viridans streptococci" is likewise inadequate, because "viridans," derived from the Latin *viridis* (green), refers to the sheen caused by partial hemolysis around alpha-hemolytic colonies on sheep blood agar. The term "oral streptococci" circumvents the dilemma of outliers in the hemolytic classification schema; however, viridans streptococci are found in sites other than the oral cavity, and nonviridans streptococcal species are frequently present in the oral cavity. In accordance with the American Society for Microbiology's most recent guidance,[256] the term "viridans streptococci" is used here for this diverse group of bacteria, with the understanding that member organisms are typically but not invariably alpha-hemolytic. We further note that viridans refers not to a species of streptococci but rather to a group of species, notwithstanding erroneous references to *Streptococcus viridans*.[278]

Streptococci have been reclassified on the basis of molecular and genetic studies[62,256]; however, this reclassification may cause clinical confusion for the short term. For example, certain small-colony beta-hemolytic streptococci, including some in Lancefield group A, are now considered to be viridans streptococci. The hope is that classification based on molecular similarities will eventually lead to a clearer understanding of the infectious diseases associated with these organisms. One should recognize, however, that the current knowledge of viridans streptococcal infections is based predominantly on studies of the alpha-hemolytic members of the viridans group.

MICROBIOLOGY

Streptococci are gram-positive, catalase-negative bacteria that are spherical or ovoid and less than 2 μm in diameter. They are facultatively anaerobic and nonmotile and do

not produce spores or gas. Some strains require an atmosphere enriched with carbon dioxide (5%). The enterococci (distinguished by their ability to grow in 6.5% sodium chloride) and lactococci (formerly Lancefield group N streptococci) were previously classified as streptococci but have now been assigned to separate genera.

Figure 84-2 is a classification schema for the clinically important streptococcal species. Hemolysis of blood agar remains a key tool for classifying streptococci. Strains that are beta-hemolytic are further characterized according to colony size and Lancefield group (a serologic classification system based on cell wall carbohydrate). Group B *Streptococcus agalactiae* strains can typically be identified by beta-hemolysis and a positive CAMP (Christie, Atkins, and Munch-Peterson) test result[256]; however, some strains of *S. agalactiae* that are alpha- or gamma-hemolytic also produce a positive CAMP test result.

Large-colony, beta-hemolytic, group A streptococci make up the species *Streptococcus pyogenes.* Most other large-colony, beta-hemolytic streptococci are group C or G streptococci, and they are occasionally pathogenic. Small-colony, beta-hemolytic streptococci, including groups A, C, G, and F and strains that cannot be grouped, are members of the *Streptococcus milleri* subgroup of viridans streptococci. Among the alpha- or gamma-hemolytic streptococci, *S. agalactiae* (group B streptococci) and *S. pneumoniae* are generally identified by positive CAMP and optochin test results, respectively. Bile solubility confirms an optochin-susceptible isolate as *S. pneumoniae*; however, some *Streptococcus mitis* isolates (as determined by genetic sequencing) yield similar results.[168]

Nutritionally deficient streptococci are identified by their requirement for the presence of a second bacterial species (*Staphylococcus aureus* is typically used in testing) to maintain growth on agar. These streptococci will generally grow in blood culture media in the absence of reduced nicotinamide adenine dinucleotide produced by a second bacterial species and may demonstrate some growth on agar in the absence of other bacteria. Nutritionally deficient streptococci were once classified as viridans streptococci, but more recent studies have assigned these organisms to a new genus: *Abiotrophia adjacens* and *Abiotrophia defectiva.*[153] With the exception of *Enterococcus* spp., streptococci that are alpha- or gamma-hemolytic, possess Lancefield group D antigen, and are bile esculin positive may be tentatively identified as *Streptococcus bovis.* This species was once considered a viridans streptococcus but is now classified separately.

Strains of one species of group C streptococci, *Streptococcus dysgalactiae*, are alpha- or gamma-hemolytic. These strains must also be distinguished from the viridans group. A species once included in the viridans group, *Streptococcus morbillorum*, was reclassified as *Gemella morbillorum.*[157] The remaining streptococcal organisms may tentatively be identified as viridans group streptococci. Thus, in practice, viridans streptococci continue to be characterized by the absence of features that distinguish other major streptococcal pathogens. Viridans streptococci have no characteristics that can be used to definitively confirm their identity in the standard microbiology laboratory.

Classification of species within the viridans streptococci group has also been challenging. Several schemata have been developed over the years, including those of Carlsson,[45] Coleman and Williams,[58] Facklam,[96] Ruoff and Kunz,[257,258] and Coykendall.[62] However, each of these schemata lacks reliable markers for member species, and clinical isolates are inconsistently classified as a result. Consequently, efforts to characterize the clinical features of infections according to individual viridans streptococcal species have been largely unsuccessful. Molecular and polymerase chain reaction–based taxonomies have been

used to classify viridans streptococci,[5,62,217,255,338] but these techniques are generally unavailable in the clinical laboratory. Given the current flux in the taxonomy of these organisms, the American Society for Microbiology has advocated a simplified, practical approach to classifying viridans streptococci (Table 84-5).[256] The biochemical tests available in many clinical microbiology laboratories can be used to assign clinical isolates to one of the five groups to which the 14 clinically important viridans streptococcal species belong. Rapid molecular, nucleotide sequence analysis and polymerase chain reaction–based tests are available for tentative identification of individual viridans streptococcal species.[101,110,224,258,303] However, precise identification of species currently has clinical significance only as an epidemiologic tool.

EPIDEMIOLOGY

Viridans streptococci are the predominant oral microflora of humans; they are also commonly found in other areas of the upper respiratory tract, throughout the gastrointestinal tract, and in the female genital tract. Viridans streptococci are occasionally identified as skin flora.

Viridans streptococci begin colonizing neonates shortly after birth. By 1 month of age, virtually all infants are colonized with at least one species of viridans streptococci.[221] The mix of colonizing species varies with human ontogeny. For example, *Streptococcus mutans*, a species implicated in the development of caries, is rarely found in predentate children but is commonly present after the eruption of teeth.[47,84,301] The ecology of other viridans streptococcal species also appears to be affected by the eruption of teeth.[48,84,280,301] In addition to these temporal factors in the colonization of infants and children, individual viridans streptococcal species preferentially colonize certain anatomic areas of the oral cavity and pharynx. For example, *Streptococcus sanguis* is the predominant isolate of the buccal mucosa but is rarely found on the dorsum of the tongue, where *S. mitis* is the predominant species.[105] Diet may also affect viridans streptococcal ecology. For example, the low oral pH that can result from consumption of sugar-containing beverages and other carbohydrates favors colonization with caries-producing *S. mutans*.[118,298]

Little is known about the transmission of viridans streptococci in general, but studies have shown that *S. mutans* is commonly transmitted within families, especially from mother to child, and among young school children.[4,44,76,125,259] Toothbrushes may be an important vehicle of transmission of viridans streptococci in children.[181] A normal dishwasher cycle eliminates *S. mutans* from toothbrushes.[19] The hands of hospital personnel, especially those with skin disorders such as eczema, may also be a vehicle for transmission.[55] In addition, paper dental records have been suggested as a vehicle for the transmission of viridans streptococci.[64]

Viridans streptococci play an important role in the ecology of the oral flora by protecting against potentially more invasive pathogens via colonization resistance.[18,109] This mechanism was demonstrated by a double-blind study in which patients who had completed antibiotic therapy for group A streptococcal pharyngitis were treated with either a preparation containing four species of viridans streptococci or a placebo. None of the 17 patients in the treated group experienced recurrence of group A streptococcal pharyngitis, whereas pharyngitis recurred in 7 (37%) of the 19 patients in the placebo group.[248] A second double-blind, placebo-controlled multicenter trial by the same group confirmed these findings.[249] Viridans streptococci may also contribute to colonization resistance to pathogens such as methicillin-resistant *S. aureus* in the infant oral cavity[317]; nontypable *Haemophilus influenzae*, *S. pneumoniae*, and *Moraxella catarrhalis* at the eustachian tube orifice[300]; and *Neisseria gonorrhoeae* in the female genital tract.[191] In addition to

competing for mucosal adherence sites, viridans streptococci produce hydrogen peroxide and bacteriocins that inhibit certain competing bacteria; this mechanism may also contribute to colonization resistance.[65,67,318,323] Conversion of the hydrogen peroxide to ozone in the oral cavity may play a role in colonization resistance to other bacterial species and to *Candida* species.[316]

PATHOGENESIS

Viridans streptococci are typically low-virulence organisms; when they do cause infection, it is usually nonpyogenic with the exception of infections caused by the *Streptococcus milleri* subgroup. They are implicated most often in localized infections of the sinuses and oral cavity, including the teeth, after the tissues are directly invaded by colonizing organisms. Caries is a dental disease that develops during a period of years, often in association with *S. mutans* infection interacting with other oral flora.[161] Patients with cystic fibrosis may be particularly susceptible to caries because of a decreased buffering capacity.[46] Viridans streptococci are associated with a variety of gingival diseases, possibly including gingival hyperplasia accompanying chronic phenytoin administration. In an experimental animal model, phenytoin-induced gingival hyperplasia was more advanced in rats infected with *Streptococcus sobrinus* than in uninfected control animals.[206] On occasion, viridans streptococci, usually organisms of the *S. milleri* subgroup, cause pyogenic infections, including abscesses in the brain, lung, and abdomen. An intriguing preliminary study suggested that viridans streptococcal–related dental disease is associated with the subsequent development of coronary artery disease.[173] Viridans streptococci are among the microorganisms isolated from atherosclerotic plaque, although their role in the pathogenesis of atherosclerosis is unknown.[54] Typically, viridans streptococci cause life-threatening infection only when the oral mucosa is disrupted and the host's mechanisms of microbial clearance are compromised by conditions such as neutropenia or cardiac valve disease.

It is the preponderance of viridans streptococci in the oral flora, rather than their virulence, that accounts for their predominance in infections originating in the mouth. In a study of 36 children who underwent extraction of normal or abscessed teeth, 11 (30%) had postextraction positive blood cultures, and viridans streptococci were exclusively isolated in all 11.[287] Bacteremia occurred more commonly after removal of diseased teeth (37%), but it also occurred after removal of normal teeth (23%).

Another study of 58 children who underwent dental extraction included 26 who received penicillin, amoxicillin, or erythromycin prophylaxis because of a risk of endocarditis.[61] Bacteremia was detected in only 9 (35%) of the 26 children who received prophylaxis and in 20 (63%) of 32 children who did not ($P < .05$). In this study, viridans streptococci accounted for 37 percent of the blood isolates, strict anaerobes accounted for 26.5 percent, and a variety of organisms accounted for the remainder. The number of colony-forming units per milliliter of blood ranged from 2 to 12. Even within a single colony-forming unit, more than one bacterial species was sometimes identified after subculture.

In a study from Spain, bacteremia was detected in 96 percent, 64 percent, and 20 percent of patients 30 seconds, 15 minutes, and 1 hour after dental extractions.[310] This study indicates that bacteremia after dental procedures may not be as transient as was generally believed.

A study of 30 subjects with chronic periodontitis and 30 subjects with periodontal health showed that 40 percent and 41 percent had bacteremia during dental flossing; viridans streptococci were the most common isolate in both groups.[63] Roughly half of positive subjects remained positive 10 minutes after flossing.

Although these two studies differed in the diversity of organisms isolated, both indicated that viridans streptococci are the organisms most likely to invade the blood after trauma to the oral cavity. Viridans streptococcal bacteremia also occurs commonly during orthodontic banding[95] and esophageal stricture dilation, also reflecting the predominance of these organisms in the oral and salivary flora.[344]

The ability of viridans streptococci to bind to oral mucosa, dental surfaces, and dental plaque by interaction with specific microbial and host "receptors" accounts for the preferential colonization of the oral cavity by these organisms.[321] This interaction also helps explain the localization of the various viridans streptococcal species to distinct anatomic sites as well as the involvement of ontologic factors in colonization. The precise nature of bacterial adherence to the oral mucosa is not defined but appears to involve streptococcal lipoteichoic acid.[135] Through release of modulin protein I/II, viridans streptococci induce the expression of adhesion molecules such as E-selectin and intercellular (ICAM-1) and vascular cell (VCAM-1) adhesion molecules on endothelial cells, promote transendothelial migration of neutrophils in vitro, and induce cytokine release in epithelial (interleukin-6 [IL-6]) and endothelial (IL-6 and IL-8) cells.[325,326] Orthodontic appliances favor the proliferation of *S. mutans*.[312] The host's immune status also may be an important determinant of adherence and subsequent invasion. For example, immunocompetent persons produce secretory IgA to *S. mutans*,[12] and these antibodies are capable of preventing caries.[199] Viridans streptococci within the biofilm present in dental plaque are at least 500 times more resistant to antibiotic treatment than is predicted on the basis of their susceptibility in culture medium; this finding suggests that antibiotic treatment cannot eradicate viridans streptococci from dental plaque, even temporarily.[163]

At the University of Texas M. D. Anderson Cancer Center in Houston, the incidence of viridans streptococcal bacteremia increased extraordinarily between 1972 and 1989, from 1 to 47 cases per 10,000 admissions.[86] A risk factor analysis indicated that patients were significantly predisposed to the development of bacteremia by prophylactic administration of trimethoprim-sulfamethoxazole or a fluoroquinolone, profound neutropenia, or the administration of antacids or histamine type 2 receptor antagonists.[86] Presumably, administration of the implicated antibiotics and antacids favored the overgrowth of viridans streptococci and their proliferation

throughout the gastrointestinal tract, which in turn would favor viridans streptococcal bacteremia in an immunocompromised host, especially a neutropenic host whose mucosal barrier was disrupted by cytotoxic chemotherapy. Notably, although administration of cytosine arabinoside (cytarabine, Ara-C) was identified as a major risk factor for viridans streptococcal sepsis in many other studies,* it did not emerge as a risk factor in this study.

The ability to adhere to damaged cardiac valves and vegetations is a key factor in the pathogenesis of viridans streptococcal endocarditis. Strains of viridans streptococci carried by healthy children adhered less well to buccal and endocardial cells than did strains isolated from children with viridans streptococcal endocarditis.[268,269] Lipoteichoic acid is thought to help mediate adhesion of viridans streptococci to endocardium, and the effectiveness of penicillin prophylaxis may reflect its reduction of lipoteichoic acid on the bacterial cell surface.[175]

The ability of antibiotics to alter the surface properties of bacteria, even those resistant to the bactericidal action of the drug, may be an important determinant of the effectiveness of prophylactic antibiotics.[175,276] In the host, fibronectin is an important determinant of viridans streptococcal binding to damaged endothelium. Although viridans streptococci do not bind to soluble fibronectin, a reactive fibronectin binding domain becomes available when the fibronectin molecule is immobilized, as in endocarditis.[174] Mutant viridans streptococci that were unable to bind to fibronectin were shown to be significantly less virulent in an animal model of endocarditis.[174]

The ability of viridans streptococci to induce platelet aggregation also may be a factor in the pathogenesis of endocarditis.[102,182] In viridans streptococci–challenged, anticoagulated rabbits, only microscopic vegetations developed despite fulminant sepsis, indicating inability to limit the infection. In contrast, viridans streptococci–challenged, nonanticoagulated animals tended to have large vegetations and a subacute course.[138] These findings are concordant with those of a separate study showing that the density of bacteria within vegetations was greater in viridans streptococci–challenged thrombocytopenic rabbits than in nonthrombocytopenic control animals; these results suggest that platelets limit progression of the disease.[294] Surprisingly, neutropenia appears to have little effect on susceptibility to endocarditis in animal models, although it impedes containment of the infection.[194,195]

In neutropenic cancer patients and those who have undergone bone marrow transplantation, viridans streptococci cause septic shock and adult respiratory distress syndrome (ARDS). Viridans streptococci also induce nephritis in experimental models.[6,305] Little is known about the mechanisms involved in the pathogenesis of these conditions. Viridans streptococci produce no endotoxin, and no specific exotoxins have been identified. Nonetheless, products of these organisms can activate complement[204] and induce production of tumor necrosis factor (TNF)-α and TNF-β, IL-1, IL-2, IL-6, IL-8, interferon-γ, and nitric oxide.* Strains isolated from patients with sepsis were found to induce TNF-β and IL-8 production more potently than colonizing strains isolated from healthy subjects.[285] A study of two neutropenic patients with fatal viridans streptococcal sepsis showed high blood levels of IL-6, especially late in the course of infection, whereas levels of IL-1 and TNF-α were unremarkable.[89] Viridans streptococcal lipoteichoic acid induces production of cytokines and nitric oxide in vitro,[91,204] but the clinical significance of these observations is not known. Unlike blood-borne group A streptococci isolated from patients with septic shock, viridans streptococci isolated from the blood of pediatric cancer patients with septic shock do not express superantigens in vitro.[213] Thus, intravenous immune globulin, which has been suggested as an adjuvant therapy for group A streptococcal shock, may not be effective in cases of viridans streptococcal sepsis.

CLINICAL MANIFESTATIONS

The viridans streptococcal species are diverse, and consequently the infections they cause show a variety of clinical manifestations. Typically, the viridans streptococci cause nonpyogenic infections such as bacteremia and endocarditis, whereas the *S. milleri* group (also referred to as the *Streptococcus intermedius* group) tends to cause invasive pyogenic infections, including bone infections, brain abscesses, appendicitis, and pulmonary and abdominal abscesses.[207]

Sepsis in Immunocompromised Hosts

For obscure reasons, the relative incidence of gram-positive bacterial infections, especially viridans streptococcal infections, has increased in immunocompromised hosts during the past 2 or 3 decades. Viridans streptococci were first identified as an important cause of sepsis in neutropenic patients with cancer in 1978, when 29 episodes were reported in adults and children at the National Cancer Institute[228] and 6 episodes were reported in children at the M. D. Anderson Cancer Center.[134] The significance of blood isolates of viridans streptococci in the setting of cancer had previously not been generally appreciated. The fact that no deaths occurred in the original National Cancer Institute series or in a subsequent series from that institute[253] suggested that viridans streptococci produce a benign bacteremia similar to that caused by coagulase-negative staphylococci. In contrast, three of the six children at M. D. Anderson died. Several other centers in Europe and North America have reported fulminant, sometimes fatal viridans streptococcal sepsis in patients with cancer and in patients who have received transplants.† Overall, the reported death rate associated with viridans streptococcal sepsis has ranged from 0

*References 31, 32, 42, 78, 141, 186, 196, 242.

*References 20, 91, 127, 190, 215, 282, 284, 297.

†References 11, 14, 23, 31, 32, 42, 57, 59, 86, 117, 120, 129, 140, 164, 186, 189, 223, 240, 242, 275, 283, 290, 329.

percent to 50 percent; most centers report mortality rates of approximately 10 percent. In some centers, viridans streptococci are the most common cause of fatal and nonfatal sepsis.[23,31,117,124] The incidence of viridans streptococcal sepsis appears to be higher in children than in adults.[189,290]

The oral cavity is the most common portal of entry in immunocompromised hosts. Catheter-related viridans streptococcal bacteremia is unusual as determined by quantitative culture of simultaneous peripheral and catheter blood specimens. However, because administration of antacid is a risk factor,[86] the lower gastrointestinal tract is likely to be a portal of entry in some patients taking antacids and potentially in other circumstances. Several factors predispose patients to viridans streptococcal sepsis. Profound neutropenia is clearly a predisposing factor,[31,86] although viridans streptococcal bacteremia occasionally develops in cancer patients with absolute neutrophil counts greater than 1000/mm^3. Mucositis, especially oral mucositis, is a well-recognized risk factor.* Cytarabine appears to incur a risk even greater than that caused by its induction of clinically apparent mucositis,† although this greater risk has not been observed in at least one study.[111] Chemotherapy does markedly alter the oral flora, with 25 species identified only after chemotherapy in one study.[208] The use of prophylactic trimethoprim-sulfamethoxazole or quinolones is also an important risk factor.‡ The observation that administration of acyclovir may decrease the incidence of viridans streptococcal bacteremia in transplant patients suggests that herpes simplex virus infection may be a risk factor as well.[243] Allogeneic bone marrow transplantation has also been associated with increased risk of viridans streptococcal sepsis, which increases the mortality rate by a factor of 4.[186] Development of viridans streptococcal sepsis has also been observed to be associated with menstruation.[86]

The hallmark clinical feature of viridans streptococcal sepsis in an immunocompromised host is fever that typically is high, coincides with neutropenia and mucositis, and frequently lasts for several days after viable organisms are cleared from the blood. Most patients recover uneventfully. However, fulminant septic shock may occur. Shock may appear early, although it is often delayed for 2 or 3 days after the onset of sepsis, and it occurs despite prompt sterilization of blood by effective antibiotics.[290] ARDS frequently occurs in severe cases, usually 2 or 3 days after the initial bacteremia.[11,86,302] Focal complications, including pneumonia, encephalopathy,[265] and meningitis, are uncommon. Rash and palmar desquamation may be present but are not common.[86] For unexplained reasons, the incidence of aspergillosis is increased after viridans streptococcal sepsis in children with cancer.[214]

Several studies have implicated *S. mitis* as a more pathogenic species of viridans streptococci that has a greater likelihood of causing shock and ARDS in patients with cancer,* but other studies have found no clear relationship between clinical features and species.[86] *S. mitis* is the closest known relative of *S. pneumoniae*, and the two species share numerous pathogenicity genes.[71] *S. mitis* isolated from cancer patients with sepsis has also been found to be more antibiotic resistant than other species of viridans streptococci isolated from the same patient population.[126]

Neonatal Sepsis, Meningitis, and Other Infections

Viridans streptococci are normal inhabitants of the female genital tract and are a common cause of chorioamnionitis and subsequent abortion.[10] They are also a frequent cause of neonatal sepsis and meningitis.† Viridans streptococci do not ordinarily colonize the skin of newborns and should not be dismissed as contaminants when they are isolated from normally sterile sites.[2] At some newborn centers, the incidence of bacteremia and meningitis caused by viridans streptococci has approached or exceeded that caused by group B streptococci, although viridans streptococcal infections tend to be less severe.[37,205] *Streptococcus oralis (S. mitis)* caused more than half of the cases in one study.[332] The portal of entry of the organism is generally unknown in this setting, but a fetal scalp electrode was implicated in one case.[107] Unusual manifestations in newborns include pharyngitis and epiglottitis,[34] endocarditis,[193] and conjunctivitis.[160] Viridans streptococci also account for 6 to 12 percent of community acquired bacteremias, with a higher prevalence in children than in adults.[299]

Endocarditis

Viridans streptococci are a common cause of endocarditis at all ages because of the organism's ability to adhere to diseased endocardium and its frequent implication in bacteremia after dental procedures and routine mouth care. A study at a teaching hospital in Finland found that starting in 1995, *S. aureus* overtook viridans streptococci as a cause of endocarditis.[128] However, a study in Minnesota found no significant change in the etiology of endocarditis between 1970 and 2000; viridans streptococci remained the most common cause.[309] A study in Israel noted that *Candida albicans* was the most common cause of hospital-associated endocarditis in children, whereas viridans streptococcus was the most common cause of community acquired endocarditis in children.[183] Viridans streptococci tend to cause subacute endocarditis; blood cultures may be only intermittently positive. *S. sanguis* and *S. mitis* are the species most commonly identified.[79,238,244,295,334] Complications of viridans streptococcal endocarditis include septic pulmonary emboli, congestive heart failure, pericarditis, myocardial abscess, meningitis, osteomyelitis, and glomerulonephritis.[162,238] Shock and ARDS occur in immunocompromised patients but not in immunocompetent patients with endocarditis.

Pneumonia

Pulmonary infiltrates frequently complicate viridans streptococcal sepsis in neutropenic hosts. In most cases, these infiltrates represent ARDS and not primary pneumonia. However, several cases of primary viridans streptococcal pneumonia have been reported in previously healthy persons.* In some cases, the diagnosis was supported by multiple viridans streptococcus isolates from blood in the absence of endocarditis. The incidence of viridans streptococcal pneumonia may be significantly underestimated as tracheal isolates of viridans streptococci are usually discounted as contaminants, which they may not be in all cases.[250] In children with *S. milleri* group pleuropulmonary infections, computed tomography often shows complex pleural effusion and lung abscesses, which may require drainage for optimal treatment.[165] Viridans streptococci are increasingly recognized as contributing to pulmonary infections in children with cystic fibrosis, a population with a higher prevalence of antibiotic resistance among viridans streptococcal isolates.[119,218,279] Given the increasing incidence of viridans streptococcal infection and the escalating prevalence of antibiotic resistance among these organisms, clinicians should consider viridans streptococci as potential causes of pneumonia when they are isolated in the absence of other pathogens.

Osteomyelitis and Septic Arthritis

Viridans streptococci are unusual causes of osteomyelitis and septic arthritis. Extension of an oral infection into the mandible or maxilla is the most common cause of viridans streptococcal osteomyelitis,[220] but several cases of vertebral osteomyelitis caused by these organisms have been described.† Infection of the long bones[212,241] and septic arthritis[15] occur infrequently.

Caries

Although caries was recognized as an infectious disease in 1890 by workers trained in Robert Koch's laboratory, its infectious nature is still not accepted universally.[9,13,83] Evidence that *S. mutans* is the main cause of caries in children and adults alike is substantial,‡ but other viridans streptococci, *Lactobacillus* spp., and *Actinomyces* spp. also have cariogenic potential among the more than 700 species found in the indigenous microflora.[151,236,273,322] *S. mutans*, which colonizes the oral cavity only after the eruption of teeth, has a predilection for the dental surfaces, metabolizes sucrose, and produces a strong acid that weakens the mineral matrix of teeth, allowing the organisms to penetrate the dental structure.[49,273] Fluoridation of the water supply has been credited with strengthening tooth enamel, thereby fostering resistance to the harsh acids produced by *S. mutans*.[273] Fluoride exerts potent antibacterial activity against *S. mutans*, particularly at low pH.[49,324] Thus, fluoridation of water supplies may represent, albeit in a unique form, the most widespread and successful use of antibacterial prophylaxis. Topical treatments also provide protection against the cariogenicity of *S. mutans* and in some circumstances depend on the antibacterial action of fluoride.[133,308,320,342] Short courses of oral antibiotics can substantially reduce colonization with *S. mutans* and may be an important adjunct to the treatment of caries.[289] Specially designed culture systems are available to detect and measure the concentration of *S. mutans* in plaque to monitor the effects of therapy.[35,331] Because the development of cavities typically requires a few years of infection, there is ample opportunity to interrupt the pathogenesis of this disease.[9] A study in Germany showed that a special long-term program begun during pregnancy and continued through the teenage years increased caries-free dentitions from 57 percent in the control group to 90 percent in the treatment group.[197]

Abscesses and Other Infections

Suppurative infections produced by viridans streptococci are typically caused by the *S. milleri* group: *Streptococcus anginosus*, *Streptococcus constellatus*, and *S. intermedius*. Like *S. aureus*, members of this group resist killing by polymorphonuclear leukocytes and stimulate less chemotaxis than other viridans streptococci do.[328] *S. anginosus* is particularly prevalent in odontogenic abscesses, subdural empyemas, and epidural abscesses.[123,281] Because *S. milleri* inhabits the upper respiratory tract and the gastrointestinal tract and is relatively invasive, this organism causes sinusitis, otitis media, meningitis, and abdominal, splenic, and perianal abscesses, and it is often identified in brain abscesses, sometimes in association with tongue piercing.* *S. milleri* group organisms may infect the brain through a hematogenous route that originates in the oral cavity or intestinal tract or by direct invasion through the upper respiratory tract. Sepsis is uncommon in nonneutropenic patients, usually occurring in association with an intra-abdominal source.[178,261]

Other unusual infections caused by viridans streptococci include a large outbreak of *S. mitis* pharyngitis accompanied in 50 percent of cases by a toxic shock–like syndrome.[177] Meningitis resulting from both hematogenous and direct spread has been observed in healthy adults.[176] Iatrogenic meningitis due to contamination by oral viridans streptococci may complicate lumbar puncture or other central nervous system procedures.[93,267,339] Lung abscesses caused by viridans streptococci may result from the aspiration of saliva.[147,234] Empyema and mediastinitis are other reported thoracic infections associated with viridans streptococci.[21,147] Myositis complicated by rhabdomyolysis in children with leukemia has been reported.[262] Viridans streptococci also are found occasionally in liver abscesses,[17,103,112] peritonitis,[25] appendicitis,[229] and endophthalmitis.[52] In solid organ transplantation patients, viridans streptococci are a common cause of cholangitis.[292] Molecular analysis indicates that some cases of culture-negative intracranial abscess are caused by *S. anginosus*.[225]

DIAGNOSIS

Infections caused by viridans streptococci cannot be distinguished clinically from those caused by other gram-positive and gram-negative bacteria. Collection of adequate culture specimens is essential for diagnosis. Viridans streptococcal infections are typically diagnosed by culture of blood or other normally sterile tissues. The organisms may be present in low concentration. A volume of 30 mL of blood has been suggested as the optimal volume for culture in an adult-sized patient.[271] The addition of agents that neutralize the antibacterial effects of fresh blood, such as sodium polyanethol sulfonate, significantly improves the yield of blood cultures.[272] Chemotherapeutic agents may interfere with detection of viridans streptococci in blood.[222]

Viridans streptococci are normally not members of the skin flora and should not ordinarily be considered contaminants. Viridans streptococci have been reported to cross-react with *S. pneumoniae* omnisera, potentially causing false-positive results.[137]

ANTIBIOTIC SUSCEPTIBILITY

Viridans streptococci were once considered penicillin sensitive. Today, however, penicillin-resistant and penicillin-tolerant viridans streptococci are identified worldwide as causes of sepsis, endocarditis, meningitis, and other infections, including conjunctivitis of the newborn.* Penicillin resistance occurs commonly, particularly in patients receiving long-term penicillin therapy,[8,29,219,288,293] although even short courses of antibiotics may predispose patients to colonization with resistant viridans streptococci.[94,113,202] Monthly injections of penicillin do not appear to increase penicillin resistance in oral viridans streptococci.[28] Antibiotic resistance is found more commonly in viridans streptococci isolated from children compared with adults, perhaps reflecting greater use of antibiotics in children.[74] Infection with penicillin-resistant viridans streptococci is associated with a higher risk for mortality than is infection with penicillin-susceptible strains.[73,286] All species of viridans streptococci may develop antibiotic resistance, although *S. mutans* rarely exhibits resistance.[146]

Resistance to a variety of antibiotic classes has developed during the past 2 decades,[232] although resistance is still uncommon in community residents who have not had recent antibiotic treatment.[340] Resistance to cephalosporins is widespread; the general pattern of susceptibility is that cefotaxime and ceftriaxone are usually more active than cefepime and cefuroxime, which are both more active than ceftazidime and cephalexin.[75,185,226,335] Previous cephalosporin therapy is a risk factor for cephalosporin resistance, an observation particularly relevant to patients with cancer.[39,154] Resistance to fluoroquinolones, especially ciprofloxacin and ofloxacin, is common.† Levofloxacin has greater activity against viridans streptococci than the older fluoroquinolones do, and the newer agents garenoxacin, gatifloxacin, and moxifloxacin have enhanced activity against most gram-positive pathogens, including viridans streptococci.[245-247,281] However, resistance develops rapidly when patients receive prophylactic quinolones, including levofloxacin, gatifloxacin, and moxifloxacin.[233,306] At the Mayo Clinic in Rochester, Minnesota, 6 (16%) of 37 transplant patients receiving levofloxacin prophylaxis developed viridans streptococcal sepsis (3 experienced shock); blood isolates were resistant to levofloxacin and to the newer quinolones gatifloxacin and moxifloxacin.[239] Resistance was associated with mutations in the quinolone resistance–determining region of GyrA or ParC. Resistance of viridans streptococci to aminoglycosides,[152] tetracycline,[68,75,338] trimethoprim-sulfamethoxazole,[68,72,75,338] clindamycin,[72,313,338] erythromycin,[36,68,72,332,338] other macrolide antibiotics,[7] and vancomycin[277] has also been reported. Meropenem resistance of viridans streptococci appears to increase in children with cancer who receive multiple courses of empirical therapy.[1]

The penicillin resistance of viridans streptococci appears to involve chromosomally mediated alterations in the organisms' penicillin-binding proteins.[237,343] Initially, researchers suspected that genes conferring penicillin resistance had been acquired from *S. pneumoniae*.[81] Subsequent studies, however, indicated that penicillin resistance may have evolved first in *S. mitis* and that *S. pneumoniae* might have acquired genes mediating penicillin resistance from this and other closely related viridans streptococcal species,[50,80,231] although a recent study favors the other pathway.[142] Quinolone resistance determinants are also transmitted efficiently between viridans streptococci and *S. pneumoniae*,[145] and the *mef*(E) gene, which confers resistance to macrolides, is readily transmitted from viridans streptococci to *S. pyogenes*.[149]

The clinical impact of the development of penicillin resistance among viridans streptococci has been far-reaching. The emergence of penicillin-resistant viridans streptococci may in fact be encouraging the development of vancomycin-resistant enterococci because of the increased use of vancomycin to prevent and to treat viridans streptococcal infection in patients with cancer.

Overall, vancomycin is the antibiotic most reliably active against viridans streptococci. Teicoplanin also has been used successfully to treat viridans streptococcal endocarditis.[336] Daptomycin, dalbavancin, quinupristin/dalfopristin, tigecycline, and linezolid are active in vitro against most clinical isolates of viridans streptococci,[99,148,158,201,260] although breakthrough septic shock due to resistant *S. anginosus* has been reported during daptomycin therapy,[216] and 43 percent of viridans streptococci were resistant to quinupristin/dalfopristin in a study from Finland.[172]

TREATMENT

Empirical antibiotic therapy for viridans streptococci should be based on the pattern of antibiotic susceptibility among recent local clinical isolates. Antimicrobial susceptibility testing of viridans streptococcal isolates is

*References 33, 38, 85, 98, 115, 136, 160, 170, 230, 237.
†References 51, 68, 72, 155, 266, 338.

necessary. Limited data indicate that antibiotic susceptibility testing performed with the E-test is well correlated with agar dilution susceptibility testing.[251] Although vancomycin-resistant clinical isolates are rarely identified at present, inclusion of vancomycin in susceptibility testing is advisable. For infections other than endocarditis and meningitis, single-antibiotic therapy is usually preferred. However, in neutropenic patients with cancer, restricting antibiotic therapy to drugs active against gram-positive bacteria may increase the risk for gram-negative bacterial infections.[227] Some investigators have advocated reserving vancomycin for neutropenic patients with shock or ARDS,[313] whereas others have advocated inclusion of vancomycin in initial empirical therapy for patients with fever and neutropenia.[87,275] Viridans streptococcal sepsis may occur in neutropenic patients despite ongoing antibiotic therapy with β-lactam agents to which the organisms are susceptible in vitro[275]; however, this phenomenon has not been observed during vancomycin therapy, supporting the use of this antibiotic for viridans streptococcal sepsis in neutropenic patients. In addition, various methods to measure the susceptibility of viridans streptococcus to various antibiotics commonly yield discrepant results.[179]

Combination therapy is often advocated for treatment of viridans streptococcal endocarditis[30,104,188,327] and may be considered for treatment of meningitis, especially when the pathogen is penicillin tolerant.[92] A combination of either penicillins and aminoglycosides or of vancomycin and aminoglycosides is used most commonly. Penicillin and vancomycin are thought to increase the uptake of aminoglycosides, thereby providing synergistic bactericidal activity.[341] However, a meta-analysis of five clinical trials failed to identify any overall improvement in the outcome of patients with endocarditis who were treated with β-lactam and aminoglycoside combination therapy versus β-lactam monotherapy.[97] Vancomycin monotherapy has been successfully used to treat patients with penicillin-resistant viridans streptococcal endocarditis[139,159]; monotherapy with linezolid[211] or ceftriaxone[159,274] has also been used successfully.

Frequent dosing of antibiotics is generally recommended. However, because viridans streptococci exposed to combinations of penicillin or cephalosporin plus aminoglycoside appear to be susceptible to a postantibiotic effect,[43,156,166] longer dosing intervals may be satisfactory, although data are currently insufficient to support a recommendation. Viridans streptococcal endocarditis is usually treated for 4 to 6 weeks; the duration of therapy for infections at other sites has not been studied but can generally be guided by site-specific practice and individual clinical response.

In the treatment of endocarditis, penetration of antibiotics into the fibrin vegetation may be markedly impeded. Viridans streptococci produce an exopolysaccharide composed predominantly of dextran, which may limit penetration. Experimental studies indicate that the extent of exopolysaccharide production by viridans streptococcal strains affects the success rate of antimicrobial therapy.[235] Administration of dextranase to animals with experimental viridans streptococcal endocarditis enhances antibiotic efficacy, consistent with this observation.[198] In the future, such adjuvant therapies designed to reduce the size or density of valvular vegetations may offer promise for patients with endocarditis who are not helped by conventional antibiotic therapy.

Another setting in which adjuvant therapy may be considered is viridans streptococcal sepsis in neutropenic patients who have received cytarabine chemotherapy. One uncontrolled trial suggested that the early addition of high doses of corticosteroids to the antimicrobial therapeutic regimen may reduce the incidence of associated ARDS and death.[77] However, data are insufficient to recommend this approach routinely.

PREVENTION

Attempts to prevent viridans streptococcal infection have focused on three distinct settings: prevention of caries, prevention of endocarditis, and prevention of sepsis in neutropenic patients with cancer. Efforts have been successful in the first two settings. However, the emergence of penicillin-resistant viridans streptococci and concern about the future emergence of vancomycin resistance highlight the need for new approaches to prevent infection with these ubiquitous organisms. In developing such methods, investigators should keep in mind that the resistance to colonization provided by viridans streptococci can protect the host from more virulent pathogens (see Epidemiology).

The incidence of caries in the United States has been sharply reduced by fluoridation of water supplies, inclusion of fluoride in toothpaste, and modification of diet (e.g., use of sugar substitutes). Fluoride acts as an antibacterial agent that also strengthens the resistance of teeth to invasion by bacteria. The use of dental varnishes, gels, and rinses that contain fluoride or other antibacterial agents such as chlorhexidine or vancomycin may be beneficial in selected cases.[100,150,187,210] *Streptococcus salivarius*, a relatively nonpathogenic organism that produces potent bacteriocins, has been proposed for study as a probiotic.[263] There is evidence for and against the use of xylitol gum to reduce the levels of *S. mutans* in the oral cavity.[132,270]

The American Heart Association has led a successful effort to prevent endocarditis by the administration of systemic antibiotic prophylaxis to patients with known endocardial defects who are undergoing dental procedures.[66] These efforts are aimed especially at preventing viridans streptococcal endocarditis, and penicillin is the antibiotic most commonly used. The mechanism or mechanisms by which antibiotic prophylaxis prevents endocarditis are not completely understood. In animals, endocarditis can be prevented by administration of bacteriostatic antibiotics and by maintenance of serum levels of bactericidal antibiotics that are well below the minimum inhibitory concentration for the colonizing viridans streptococci.[114] Vancomycin has been observed to prevent development of vancomycin-tolerant *S. sanguis* endocarditis in experimentally challenged animals without reducing the incidence or level of bacteremia; thus, antibiotics may prevent endocarditis by reducing bacterial adherence to endocardium.[22] This hypothesis is

supported by a study in which 21 percent of children receiving antibiotic prophylaxis developed bacteremia, in some cases with antibiotic-resistant organisms, but endocarditis rarely occurred.[131] However, studies in animals have indicated that the probability of preventing endocarditis is related to the antibiotic susceptibility of the challenging streptococcal strains.[131] A study from Sydney found that 11 of 30 patients undergoing dental scaling developed viridans streptococcal bacteremia after mouth rinsing for 2 minutes with normal saline, whereas none of 30 patients developed viridans streptococcal bacteremia after rinsing with 7.5 percent povidone-iodine.[53] This provides a promising alternative, given the increasing resistance to antibiotics found in oral flora.

Prophylaxis should be carefully targeted[311] and administered immediately before dental procedures. An increase in the number of blood-borne antibiotic-resistant viridans streptococci can be detected within 6 hours of antibiotic treatment and persists for 9 days or longer.[169] Experimental studies of the prevention of endocarditis by antibiotic administration *after* challenge with bacterial inocula have yielded inconsistent results,[24,144,180] and the clinical utility of this approach is unknown. Topical treatment with vancomycin or chlorhexidine has been advocated as an adjuvant in preventing endocarditis, but its efficacy is unproven.[296,337]

In recent years, viridans streptococcal infections have presented a major problem in neutropenic patients with cancer and in patients who have received bone marrow transplants. Because penicillin-resistant viridans streptococci are widespread, some cancer centers include vancomycin in the initial empirical antibiotic regimen for febrile neutropenic patients.[275] In addition, despite concern about promoting vancomycin resistance, bone marrow transplant physicians are administering intravenous vancomycin prophylactically to high-risk patients in an effort to prevent viridans streptococcal sepsis; results of an observational cohort study support this practice.[143]

Uncontrolled trials of oral vancomycin paste[16] and vancomycin mouthwash[40] in children receiving cytotoxic chemotherapy suggested their efficacy in preventing viridans streptococcal infection. However, an increase in colonization and infection with vancomycin-resistant enterococci is a predictable consequence of increased vancomycin use. Therefore, the Centers for Disease Control and Prevention have recommended that empirical vancomycin therapy be avoided when it is feasible and encouraged investigators to explore alternatives to the empirical or prophylactic use of vancomycin.

In a comparative trial, penicillin prophylaxis was superior to trimethoprim-sulfamethoxazole prophylaxis in preventing viridans streptococcal infections in patients with cancer, despite extensive colonization with penicillin-resistant streptococci.[122] In other studies, oral prophylaxis with penicillin or roxithromycin (a macrolide antibiotic) also appeared to reduce the incidence of viridans streptococcal infection in patients with cancer in comparison to historical controls.[69,252,286] In contrast, prophylactic ampicillin did not reduce the incidence of viridans streptococcal sepsis in patients receiving autologous bone marrow transplants, and the incidence of penicillin resistance increased.[29] Other penicillin prophylaxis trials have also observed increased penicillin resistance.[29] The Centers for Disease Control and Prevention do not recommend the routine use of penicillin prophylaxis in patients receiving bone marrow transplants.[121]

Levofloxacin prophylaxis is currently commonly used to prevent bacterial infections in adults with cancer, but there is concern that viridans streptococci rapidly develop quinolone resistance.[307] Innovative prophylactic methods and carefully designed clinical trials are needed to identify effective prophylactic measures, especially for patients at high risk, such as children undergoing chemotherapy for acute myeloid leukemia.

CHAPTER 85

Pneumococcal Infections

Stephen I. Pelton • Michael R Jacobs

The pneumococcus continues to be a leading cause of morbidity and mortality in persons of all ages, and its impact on child health is demonstrated by Elliott and Beeson's conclusion that it is one of the five pathogens that account for nearly half of infection-related deaths among children younger than 5 years of age (Fig. 85-1).[142] Pneumococcal infections include serious diseases such as meningitis, bacteremia, and bacteremic pneumonia, as well as milder but more common illnesses, such as community-acquired pneumonia, sinusitis, and otitis media. The causative agent, *Streptococcus pneumoniae*, is found in the nasopharynx of 30 percent of children in industrialized countries and as many as 80 percent of children in developing and emerging nations,* is transmitted mainly through respiratory droplets among children as well as to adult contacts, and was estimated by the World Health Organization as of 2008 to cause nearly 500,000 global deaths annually among children younger than 5 years of age.[586] Many children experience some form of pneumococcal infection (e.g., otitis media or pneumonia), but sepsis or meningitis occur in few. The continued incidence and severity of pneumococcal disease, coupled with significant case-fatality rates despite antimicrobial therapy, and the increasing prevalence of strains of pneumococci resistant to antimicrobial agents serve to underscore the necessity for ongoing surveillance and expanded research into treatment and prevention of pneumococcal infections.

HISTORY

Pasteur and Sternberg, working independently in 1880 and 1881, discovered the pneumococcus. Pasteur called the organism "microbe septicémique de la salive," and Sternberg called it "*Micrococcus pasteri.*" Each researcher recovered pneumococci from rabbits injected with human saliva. Friedlander demonstrated pneumococci in tissue from humans with pneumonia in 1882 and, in the following year, found them in most cases of acute pneumonia. Friedlander described both the characteristic capsule and colonial morphologic features of pneumococci and, in 1884, recovered pneumococci from the blood of patients with pneumonia for the first time. During the next few years, pneumococci were found in virtually all types of infection, including meningitis and otitis media. By 1890, researchers had established the pneumococcus as the most common cause of acute pneumonia, and, hence, the term *pneumococcus* emerged. In addition, the pneumococcus became recognized as a principal cause of meningitis and other serious infections. In 1926, the pneumococcus was called *Diplococcus pneumoniae* because it usually appears in pairs. In 1974, it was renamed *Streptococcus pneumoniae* because it forms long chains when grown in liquid medium.

Early researchers immunized animals with cell-free filtrates of pneumococci, demonstrated that serum from immune animals could protect against experimental pneumococcal infection, deduced the role of immunity in promoting phagocytosis, and noted agglutination of pneumococci by serum from immune animals. In 1897, Pane treated humans suffering from pneumonia with serum from such animals. By 1900, researchers had laid the foundation for immunotherapy for pneumococcal pneumonia, the only effective treatment until the advent of chemotherapy. Investigators noted that agglutination of pneumococci appeared to depend on the strain isolated. In 1910, Neufeld and Haendel classified pneumococci into several discrete serotypes on the basis of the appearance of capsular swelling (the quellung reaction). Only strains exposed to homologous serum showed capsular swelling. Their work made possible all subsequent epidemiologic investigations of pneumococcal infection, immunotherapy with type-specific serum, and the development of vaccines. The original classification of pneumococci was limited to types I, II, III, and IV (others). Currently, 93 serotypes have been identified, and certain serotypes have proved to be more virulent than others, with virulence depending, to some extent, on the species of animal infected.

The use of antisera for the treatment of pneumococcal pneumonia proved strikingly effective when type-specific sera were administered. As early as 1913, Cole and associates showed that treatment with antisera lowered fatality rates from 25 to 30 percent to 10.5 percent. In addition to allergic reactions, difficulties associated with this treatment included the necessity of identifying the causative serotype, the need for the earliest possible administration of antisera, and the availability of antisera to only types I, II, and III. White compared the efficacy of early antisera therapy and found that 403 of 1614 (25.0%) patients who did not receive any therapy died, 32 of 377 (8.5%) who received therapy within 3 days of onset died, and 24 of 127 (18.9%) who received therapy 4 or more days after onset died. Unfortunately, therapy with antisera had no beneficial effect on pneumococcal infections such as meningitis and endocarditis. Despite these drawbacks, the use of antisera soon became widespread. The advent

*References 5, 19, 100, 112, 115, 149, 156, 179, 203, 313, 351, 361, 598.

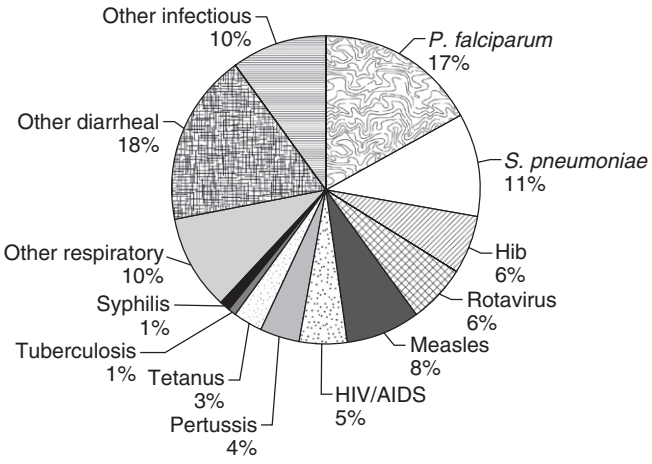

FIGURE 85-1 ■ Pathogen-specific infection-related mortality among children aged younger than 5 years. Among deaths from respiratory infection, 41% were attributed to *Streptococcus pneumoniae.* (From Elliott SR, Beeson JG. Estimating the burden of global mortality in children aged <5 years by pathogen-specific causes. *Clin Infect Dis* 2008;**46**:1794-5.)

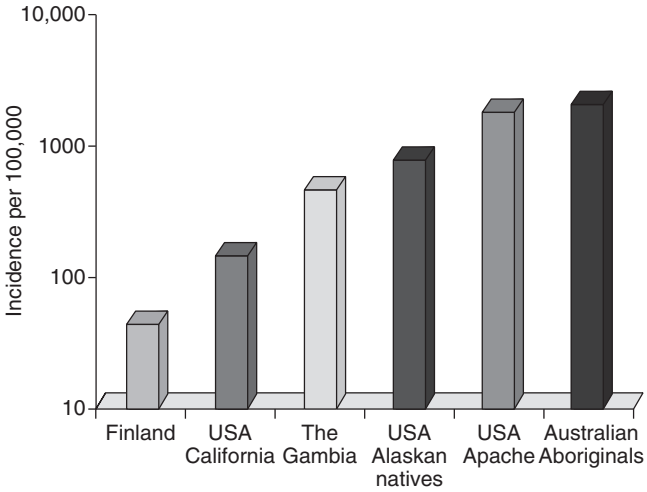

FIGURE 85-2 ■ Incidence of IPD in children age younger than 2 years in The Gambia and in various high- or low-risk populations. (From Greenwood B. The epidemiology of pneumococcal infection in children in the developing world. *Philos Trans R Soc Lond B Biol Sci* 1999;**354**:777-85.)

of chemotherapy—first with sulfa compounds, then penicillin—was followed by a precipitous decline in the use of antisera. Antimicrobial agents killed or inhibited pneumococci, regardless of serotype, and cured patients with previously incurable localized infections.[576] Coincident with research resulting in the use of antisera came research into the efficacy of pneumococcal vaccines. Proof of efficacy lagged, and indisputable evidence of protection induced by vaccination was not available until 1945. The ability of pneumococci to cause epidemic pneumococcal pneumonia in young men crowded into army camps or gold mines allowed large-scale trials to be performed. Highlights of the development of effective vaccines include the trial of Wright and associates[587] in South Africa beginning in 1911. With the use of a vaccine made with whole, killed pneumococci, this trial produced inconclusive results. Many trials followed, with some showing trends toward protection. In 1923, Heidelberger and Avery[223] published their classic article in which they stated that protective antibodies were reactive with surface capsular polysaccharides. In 1930, Francis and Tillett[166] showed capsular polysaccharides to be immunogenic for humans. Ekwurzel and colleagues[141] used a vaccine containing such polysaccharides during 1933 to 1937 and showed it to be effective. Smillie and associates used a preparation of serotype 1 polysaccharide to abort a hospital epidemic of pneumonia at a state hospital in Worcester, Massachusetts.[499]

Although many of these studies suggested that specific pneumococcal polysaccharide antigens could confer protection against severe pneumococcal infection, not until 1945, in a trial performed on U.S. Army and Air Force recruits, were they finally proved by MacLeod and associates to do so.[337] This trial showed vaccination to be strikingly effective in preventing pneumococcal pneumonia caused by serotypes contained in the vaccine but not in preventing disease caused by other serotypes, thus showing serotype-specific protection.

Regrettably, interest in vaccination waned rapidly with the general availability of penicillin, and manufacturers voluntarily withdrew their vaccines from the market. This unfortunate attitude persisted for the next 2 decades until the inability of chemotherapy to prevent many deaths from pneumococcal disease was recognized.[34] The rapid development and spread of antibiotic resistance among many clinically important strains further emphasized that prevention could be more effective than treatment for pneumococcal disease. Fortunately, a few farsighted individuals continued to maintain surveillance of the serotypes causing human disease, and their work allowed the reintroduction of pneumococcal vaccines. The current status of vaccines is discussed later in this chapter. Interested readers should consult both White's *The Biology of Pneumococcus* and Heffron's *Pneumonia, with Special Reference to Pneumococcus Lobar Pneumonia*, as well as a comprehensive review by Watson and colleagues, for a complete account of the long and fascinating history of this organism.[222,568,576]

EPIDEMIOLOGY

The incidence of pneumococcal disease is highest in children younger than 2 and adults older than 65 and varies substantially by country, by individual health status, and by season. The highest rates are observed in infants but decrease rapidly by 5 years of age. Greenwood reported that the incidence of invasive pneumococcal disease (IPD) in children younger than 2 years of age varies 10-fold, from less than 100 cases/100,000 in Finland to more than 1,000 cases/100,000 in Australian Aboriginal children (Fig. 85-2).[201] In part, the variability reflects the increased risk among children with sickle-cell disease or human immunodeficiency virus (HIV) infection, indigenous pediatric populations such as Native Americans, Inuits, or Aborigines, and malnourished children, but

because IPD impacts primarily healthy children the susceptibility of high-risk groups to infection does not explain the large geographic differences in incidence. Specific populations can have rates of IPD that are as much as 100-fold greater than those in age-matched healthy children residing within the same country. The incidence of IPD is also correlated with standard of living, with children in more industrialized countries having less disease than those living in less industrialized countries or in less privileged populations. The incidence of IPD in children younger than 5 to 6 years in western Europe (e.g., Finland, the United Kingdom, Germany, Switzerland, Denmark, Spain) was lower than 25 cases/100,000 population per year in various studies; in Chile, Australia, and New Zealand, it was 25 to 60 cases/100,000; and during the same period in the United States, the range was 65 to 75 cases/100,000.[218,245] The rates of IPD in U.S. children appear to be atypical, with higher rates reported than in comparable industrialized nations, although rates of pneumococcal meningitis appear more similar across countries.[218,338] The difference in U.S. incidence rates is most likely a reflection of the higher use of blood cultures in nontoxic febrile infants and toddlers in the U.S. than elsewhere.

Despite the high risk among children with specific comorbid illnesses, the majority of cases occur in healthy infants and toddlers. Such children represent an immunologically naïve population susceptible to bloodstream invasion or direct invasion of the lower respiratory tract. Differences in the proportion of disease by age also vary globally. In The Gambia and comparable countries, a larger proportion of disease occurs in children younger than 5 months of age compared with representative populations of U.S. children (Fig. 85-3). Similarly, in many countries, colonization is more prevalent and begins earlier, usually in the first months of life, compared with industrialized countries.[5]

Because virtually all children carry pneumococci belonging to several serotypes during their childhood, a focus on the epidemiology of carriage is warranted. In a study conducted in the United States, the prevalence of nasopharyngeal carriage in preschool children was 38 to 60 percent versus 29 to 35 percent and 9 to 25 percent in elementary school and junior high school students, respectively.[225] The prevalence in adults with no children at home was 6 percent. In studies in closed populations such as kibbutzim in Israel or a poor and crowded black community in southern Israel, the same differences between children and adults were noted.[66,111] Contact with young carriers increases the carriage rates in older children and adults. In the United States, although adults with no children had a carriage rate of 6 percent, the carriage rate increased to 29 percent when children were present at home. Similarly, primary school-aged children who have siblings younger than 2 years old carried *S. pneumoniae* more often than did those without young siblings.[334] In a study in Costa Rica, cultures in mother-child dyads showed an increased prevalence of carriage: from 6 percent at 1 month of age to 39 percent at 12 months of age. At the same time, carriage in mothers increased from 0 to 9.8 percent, thus supporting that pneumococci are transmitted from infants to adults, in this case mothers.[555] In a Swedish study, the observed average duration of carriage was longer in children who had family carriers of the same serotype and, therefore, was suggestive of rapid recirculation in the family.[140]

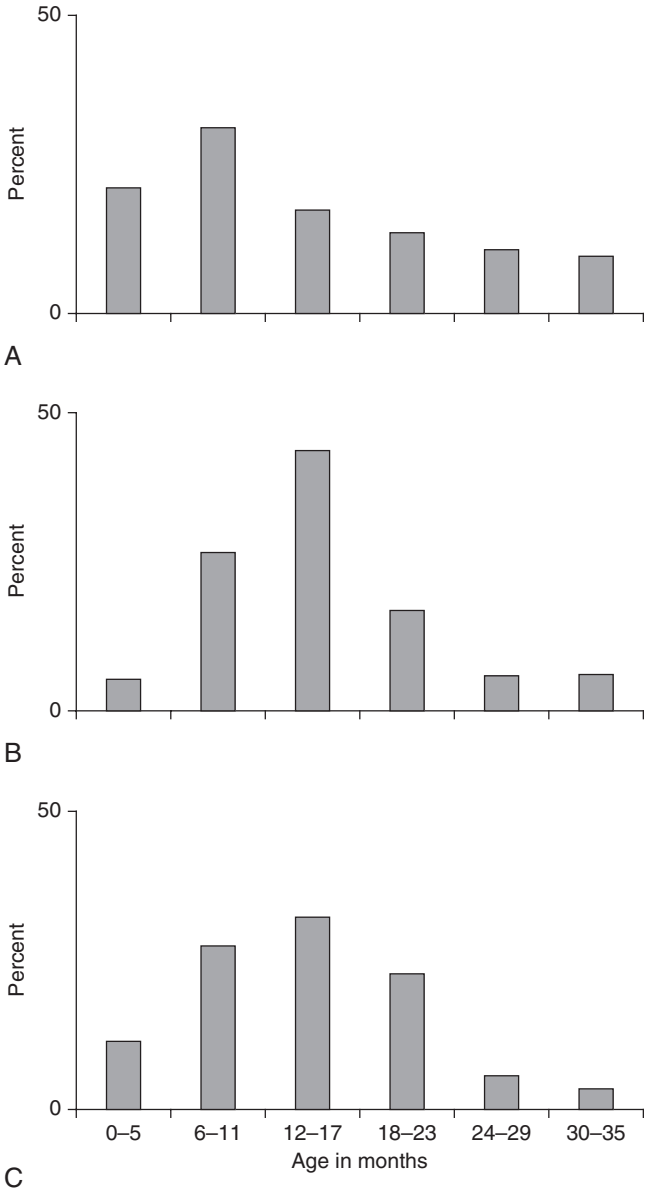

FIGURE 85-3 ■ Age distribution of IPD in young children in (**A**) The Gambia and high-risk (**B**) and low-risk (**C**) communities in the United States. (From Greenwood B. The epidemiology of pneumococcal infection in children in the developing world. *Philos Trans R Soc Lond B Biol Sci* 1999;**354**:777-85.)

Acquisition of *S. pneumoniae* may occur during the very first days of life. In infants aged 2 months, the prevalence of carriage ranges from less than 15 percent in most developed countries to greater than 60 percent in developing countries.[19] Colonization peaks toward the second to third year of life.[115,200,224] The relationship of age to carriage is not understood, but it depends, at least in part, on the development of specific anticapsular antibodies.[198,199] In toddlers vaccinated with a pneumococcal

conjugate vaccine, nasopharyngeal acquisition of new *S. pneumoniae* serotypes was inversely related to serum levels of specific antipolysaccharide IgG antibodies.[109] In another study, the presence of both circulating IgG and secretory IgA antibodies to the surface pneumococcal protein PsaA was associated with a lower prevalence of nasopharyngeal pneumococcal carriage.[438,493] A 2004 study showed that mucosal anticapsular IgA developed in response to colonization in preschool-aged children, regardless of vaccination status.[64] This phenomenon has been hypothesized to contribute to the falling carriage rates observed with increasing age.[600] Potentially, maturation of innate immunity may also contribute to the declining prevalence of colonization with increasing age; however, a specific role or mechanism has not been established.

Crowding is an important factor that facilitates the spread of *S. pneumoniae*. Therefore, one is not surprised that in the developed world the nasopharyngeal carriage rate and spread are highest in infants and toddlers attending daycare centers, with levels exceeding 90 percent in some studies, followed by those living with one or more siblings at home.[19,115,430,551] In addition, the viral infections that are very prevalent in infants and toddlers attending daycare centers enhance colonization of the nasopharynx with *S. pneumoniae*.[200,332,551] The combination of young age, poor hygienic behavior, and increased incidence of viral respiratory tract infections renders daycare centers an important site for transmission of *S. pneumoniae* from child to child and child to parent. Daycare centers, thus, are a nucleus of high carriage of *S. pneumoniae*, particularly antibiotic-resistant strains. This nucleus enables the dissemination of such pneumococci to other children, mainly young siblings of daycare center attendees.

The duration of carriage depends on age and serotype and may be related to additional factors such as antibiotic treatment, the immune status of the child, and other unknown factors. Carriage lasts longer in infants and young toddlers than in older children and adults.[110,140,198] In a study in Sweden,[140] infants were colonized for an average of 30 days and after 3 months 17 percent were carrying the same organism. In a study in the United States in adults, individual serotypes usually persisted for 2 to 4 weeks. The study showed that the pneumococcal serotype that initially colonizes infants (typically before they reach 6 months of age) can be detected for as long as 12 months (mean, 4 months).[198]

The relative risk for a specific serotype to colonize the nasopharynx of a child and its ability to cause respiratory tract or invasive infection appears to vary by serotype but not geographic location. Some serotypes, such as 6A, 6B, 9V, 14, 18C, 19A, 19F, and 23F, are among the most frequent colonizers in infants and young children in most parts of the world and thus often are considered "pediatric" serotypes.[68,111] These serotypes are acquired frequently by infants and young children and often are carried for prolonged periods. After children reach the age of 2 years, carriage of these "pediatric" serotypes declines rapidly. Although pneumococcal carriage decreases overall with age, the proportion of the "nonpediatric" serotypes increases with age. This phenomenon is demonstrated in Figure 85-4.

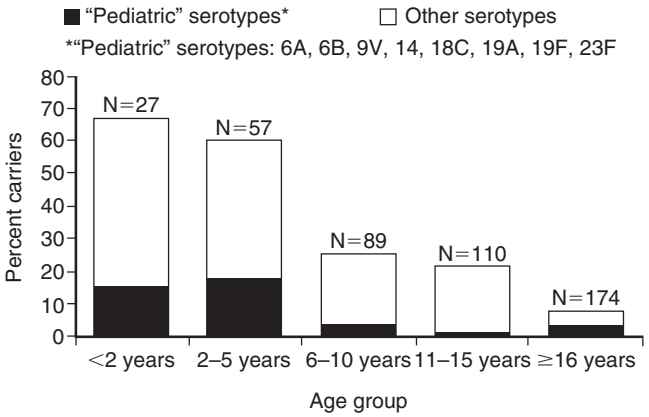

FIGURE 85-4 ■ Nasopharyngeal carriage of *Streptococcus pneumoniae* in closed community living in crowded conditions in Southern Israel. (Adapted from Dagan R, Gradstein S, Belmaker I, et al. An outbreak of *Streptococcus pneumoniae* serotype 1 in a closed community in southern Israel. *Clin Infect Dis* 2000; **30**:319-21.)

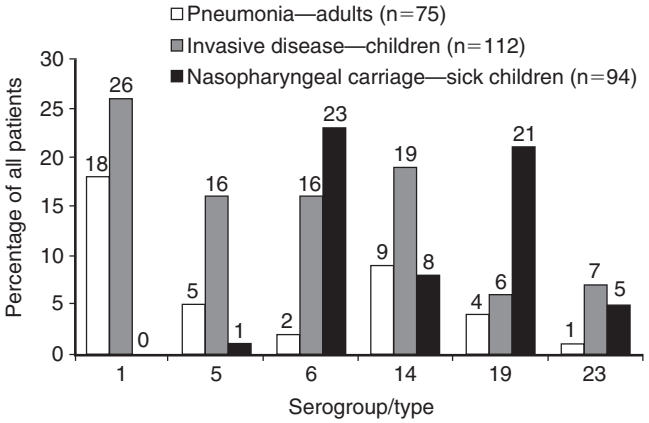

FIGURE 85-5 ■ Distribution of selected serogroups/serotypes in *Streptococcus pneumoniae* isolates from adults with pneumonia, children with IPD, and nasopharyngeal specimens from sick children in Kenya. (Adapted from Scott JAG, Hall AJ, Hannington A, et al. Serotype distribution and prevalence of resistance to benzylpenicillin in three representative populations of *Streptococcus pneumoniae* isolates from the coast of Kenya. *Clin Infect Dis* 1998;**27**:1442-50.)

In contrast to the "pediatric" serotypes, serotypes such as 1, 5, 7F, and 12 are carried infrequently and are eliminated from the nasopharynx rapidly. However, these serotypes are able to cause disease and even clusters or epidemics.[70,111] The different distribution of serotypes among colonized children, children with invasive infections, and adults with pneumonia is depicted in Figure 85-5.[480]

Although most colonization occurs without the development of disease, prospective, longitudinal studies have suggested that most systemic infections develop soon after colonization by a new pneumococcal serotype.[149,196,198] Some carriers are protected from invasive disease by the development of circulating antibodies. However, such antibodies do not always protect against

invasion of contiguous sites. Other investigators have shown that a substantial number of pneumococcal otitis media cases occur at any time during nasopharyngeal colonization by a specific serotype.[516]

One of the serious problems with pneumococcal strains clearly is the emergence of resistance to more than one antibiotic class.[251] The observed linkage between antimicrobial resistance to multiple antibiotic classes explains why the use of one antibiotic may result in carriage of *S. pneumoniae* resistant not only to the antibiotic to which the host was exposed but also to other, unrelated classes of antibiotics. In 1993, approximately a fifth of the pneumococcal strains in Iceland were penicillin nonsusceptible and 80 percent of them were multidrug resistant. When the risk for carriage of penicillin-resistant *S. pneumoniae* was investigated, a clear association was found not only with use of β-lactam drugs but also with the use of trimethoprim-sulfamethoxazole and erythromycin.[24] After treatment of otitis media, carriage of trimethoprim-sulfamethoxazole-resistant *S. pneumoniae* was found in 23 percent of patients by day 6 and in 33 percent by day 40. Additionally, non-penicillin-susceptible *S. pneumoniae* was carried at these times by 26 and 43 percent of children, respectively. This remarkable promotion of colonization with penicillin-resistant strains by trimethoprim-sulfamethoxazole treatment occurred because many strains were resistant to both penicillin and trimethoprim-sulfamethoxazole.

The dramatic change in nasopharyngeal flora after initiation of antibiotic therapy has two important consequences. First, previous treatment predisposes patients to new infections with more resistant organisms.[24] Antibiotic treatment not only can increase nasopharyngeal carriage of antibiotic-resistant *S. pneumoniae* but also can induce subsequent infection of the middle ear with a resistant strain within a few days.[112] Second, the increased prevalence of antibiotic-resistant *S. pneumoniae* in the nasopharynx may increase transmission in crowded conditions such as extended families and daycare centers.* The widespread use of antibiotics is likely to be responsible for the increase in antibiotic-resistant *S. pneumoniae*, especially in crowded populations, thus creating a vicious cycle that is difficult, if not impossible, to overcome (Fig. 85-6).[552]

Since the use of pneumococcal conjugate vaccine has become widespread in the United States, the serotypes found most commonly in nasopharyngeal colonization have been replaced by nonvaccine serotypes. A study evaluating nasopharyngeal colonization in 16 Massachusetts communities during 2001 to 2004 showed a decrease in serotypes found in the 7-valent pneumococcal conjugate vaccine (PCV7) from 36 percent to 14 percent along with an increase in non-PCV7 serotypes from 34 percent to 55 percent.[242] Another study showed that 25 percent of children colonized with pneumococci carried antibiotic-resistant, nonvaccine serotypes, including serotypes 19A and 35B, rarely detected before introduction of the pneumococcal conjugate vaccine. Further changes in the distribution of pneumococcal serotypes, specifically types 19A, 7F, and 6A, subsequent to the implementation of universal vaccination of children younger than 5 years of age with the 13-valent pneumococcal conjugate vaccine (PCV13) have been observed.[335] Both a reduction in overall carriage of the unique PCV13 serotypes as well as specific declines in serotypes 19A and 7F have been significant.

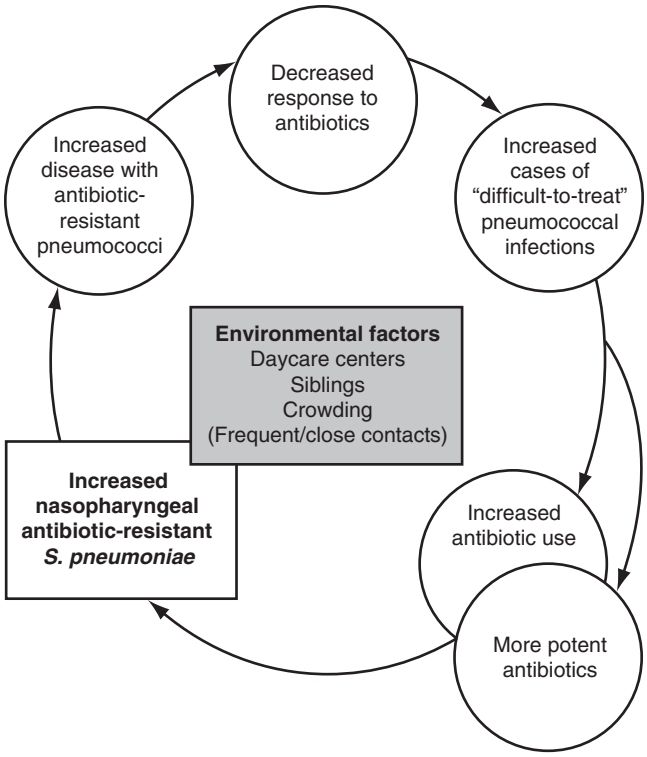

FIGURE 85-6 ■ Chain of events that create a viscous cycle in which treatment with antibiotics increases nasopharyngeal carriage of antibiotic-resistant pneumococci, which decreases responsiveness to antimicrobial treatment. The decreased responsiveness results in use of more potent antibiotics, which continues the cycle.

Risk Factors for Pneumococcal Infection

Demographic Features

Age. Young age is a major risk factor for pneumococcal infection because of immunologic immaturity and the absence of acquired immunity. The relationship between age and the development of protective immunity to pneumococcal infection was published in 1932 by Sutliff and Finland (Fig. 85-7).[515] Maternal antibody, passively transferred to the fetus, protects against invasive infection in the first few months of life. These antibodies decay over the first few months, and the incidence of IPD increases, peaking between 12 and 18 months of age, presumably as specific immunity is acquired after exposure. Following the introduction of pneumococcal conjugate vaccine (PCV), the age distribution has changed, with the peak incidence now between 6 and 12 months of age.[593] This represents the described naïveté of the infant immune system and the acquisition of protective

antibody after immunization, with two doses of PCV administered in the first 4 months of providing protection.[343,362,578] As described earlier, IPD in developing countries occurs earlier in life. It is hypothesized that this is related to earlier and more intense exposure to pneumococci in such children.[5]

Gender. In most surveillance studies of pneumococcal disease there is a greater proportion of males than females. Yildirim and colleagues reported that the proportion of male cases was significantly higher (58.5% vs. 41.5%; $p = .01$), but gender-specific incidence rates were not significantly different.*

Race/Ethnicity. The incidence of pneumococcal bacteremia and meningitis in Alaskan Native children younger than 5 years ranges from 598 cases/100,000 population in those 6 to 11 months of age to 56 cases/100,000 population in those 36 to 47 months of age, which is approximately four times the incidence in similarly aged non-Alaskan Native/non-American Indian children.[122] The highest incidence for any ethnic group in the United States is found in Navajo and Apache populations living on reservations in the southwestern United States. The incidence in children aged 1 to 2 years in these populations ranges from 557 to 2,396/100,000.[102,398] Among children younger than 5 years, the incidence of IPD in African American children in the United States is two to three times higher than that in white children of the same age.[50,72,215,452] In a case-control study of risk factors for the development of invasive disease in young children, the association of race with disease risk was not statistically significant in an analysis that controlled for socioeconomic status.[322] However, other studies have reported persistence of increased risk even when controlling for income.[72,91,157,215,226] The reasons for the increased incidence in some populations in comparison to others in the United States are unclear.

In other geographic regions, differences among populations also can be observed, again being higher in populations that live in underprivileged conditions, which raises the question of the importance of genetic versus environmental risk factors. In southern Israel, the incidence of pneumococcal invasive infection during the first year of life in Bedouin infants (a population with a lifestyle, birth rate, and general disease incidence similar to that of the developing world) was fourfold higher than in Jewish infants (a population with standards of living comparable to the middle/low social class in the developed world).[168]

In New Zealand, when Maoris, Pacific Islanders, and others were compared, incidence rates of IPD in the first year of life per 100,000 population were 153, 276, and 52, respectively. These rates in children younger than 5 years were 67, 117, and 36 per 100,000, respectively.[558]

Seasonality

Pneumococcal infection occurs in a seasonal pattern, with increased cases of invasive infections, pneumonia, and otitis media between September/October and April/May in the Northern Hemisphere, with the opposite picture in the Southern Hemisphere. Peak incidence often occurs from December through February (Fig. 85-8).[134] The same seasonal variation in nasopharyngeal

*References 70, 135, 219, 358, 387, 407, 449, 488, 527, 593.

carriage of pneumococci is also observed, with lowest rates in the summer months.[200,332] This pattern is likely related to the seasonal variations in viral respiratory tract infections, which play an important role increasing pneumococcal carriage and subsequent infection, and to attendance at school and daycare centers. However, other factors are likely to be important. In one study, adults had a higher incidence of pneumococcal disease after school holidays and thus presumably from increased contact with children.[565] In Israel, the Jewish and Bedouin populations in southern Israel demonstrate distinct and different seasonal patterns. In the Jewish population the pattern appears similar to that of traditional Western populations with distinct seasonal variation. The Bedouin live in crowded and poor hygienic conditions with a high birth rate and a disease pattern similar to that in the developing world, without a clear pattern of seasonality.[323]

Lack of Breast-Feeding

Breast-feeding may be protective against pneumococcal infection. The reduction in colonization and decreased attachment to pharyngeal cells is thought to be mediated through several components of the immune system, including secretory IgA, lactoferrin, and lysozyme. Some studies have suggested that breast-feeding protects against otitis media,[20] but others have failed to show this effect.[47] Studies in the United States demonstrated a protective effect of breast-feeding against IPD in children in the general population[47] and in Alaskan natives.[178] However, in Finland no protective effect was observed.[520]

Crowding

Crowding contributes to many factors that increase the risk for acquiring pneumococcal infection, including viral infections, poor hygiene, and potentially increased person-to-person transmission of *S. pneumoniae*. Attendance at daycare centers was the most important risk factor for acquiring IPD in children and infants in several studies.* In a recent population-based, case-control study, adults aged 18 to 64 years who lived in households that included children attending daycare were at greater risk for acquiring IPD.[393] In developed countries, attendance at daycare centers is also the most important risk factor for acquiring acute otitis media (AOM), including pneumococcal otitis.[386,460]

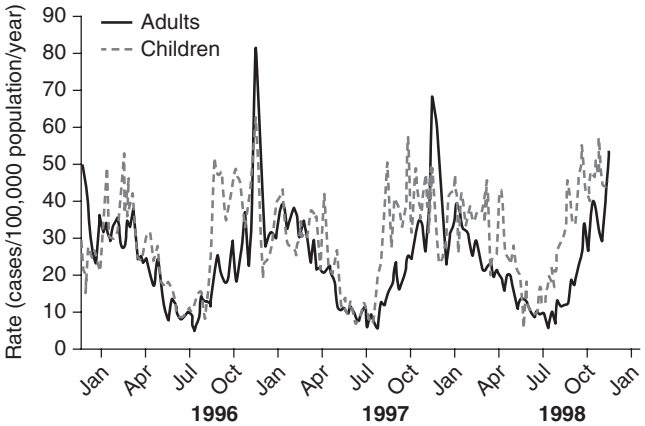

FIGURE 85-8 ■ Weekly rates of invasive pneumococcal disease in children (*dotted line:* ages birth to 17 years), and adults (*solid line:* age >18 years) in the United States, 1996 to 1998. (From Dowell SF, Whitney CG, Wright C, et al. Seasonal patterns of invasive pneumococcal disease. *Emerg Infect Dis* 2003;**9**:573-9.)

Immunocompromising Conditions

Congenital and Acquired Absence of Spleen or Splenic Function

The spleen is critical for the clearance of pneumococci from the bloodstream.[514,566] Children in whom the spleen is absent or dysfunctional are at risk for the development of overwhelming pneumococcal infection. In children with absence or dysfunction of the spleen, the mortality rate is multifold higher. Schutze and colleagues reported 27 percent mortality from prospective surveillance of eight U.S. children's hospitals.[478] Splenic dysfunction is also regarded as explaining the increased incidence and severity of pneumococcal bacteremia in sickle-cell disease and other sickle hemoglobinopathies (e.g., hemoglobin SC disease or S-β-thalassemia).[414,478,596] Children with hemoglobin SC disease, thalassemia, and other hemaglobinopathies demonstrate a higher incidence of IPD compared with healthy children, albeit lower than in persons with sickle-cell disease.[308,537] Other factors that contribute to the high incidence and poor outcome for pneumococcal infection in persons with sickle-cell disease include low levels of circulating antibodies and complement deficiency.[414,581] Penicillin prophylaxis is effective in reducing the risk for pneumococcal disease in children with absent or abnormal splenic function; however, the rate of disease remains increased compared with healthy children. PCV has been demonstrated to be immunogenic and effective in reducing disease due to vaccine serotypes in children with hemoglobinopathies (Fig. 85-9).[8,209,553] However, increased rates of disease due to serotypes not contained in the current vaccines are observed.†

Defective Antibody Formation

Reduced antibody formation is associated with increased risk for pneumococcal infection. Congenital agammaglobulinemia, acquired common variable hypogammaglobulinemia, and defective antibody production associated with diseases such as malignancies and human immunodeficiency virus (HIV) infection are associated with increased risk for pneumococcal disease.[106,545] In the era preceding the introduction of highly active antiretroviral treatment (HAART), HIV-infected children had a 100- to 1000-fold increase in incidence compared with healthy children.‡ In one study, the incidence of IPD was 6.1 cases/100 patient-years in HIV-infected children through the age of 7 years.[349] Despite the

Incidence of invasive pneumococcal disease among individuals with sickle cell disease before and after the introduction of the pneumococcal conjugate vaccine. *Clin Infect Dis* 2007;**44**:1428-33.)

introduction of HAART, HIV-infected African children remain a high-risk group for IPD.[392]

Neutropenia and Neutrophil Dysfunction

The risk for pneumococcal disease is not uniform across all neutrophil abnormalities. Primary and secondary neutropenia, such as cyclic neutropenia, drug-induced neutropenia, and aplastic anemia, are associated with an increased incidence of severe pneumococcal infection. However, the incidence is not increased in other granulocyte dysfunction syndromes such as leukocyte adhesion deficiency syndromes.[16,171]

Genetic Variation in Mannose-Binding Lectin (MBL)

Approximately 5 percent of the population in Europe and North America and an even larger population in many developing countries are homozygous for MBL codon variants. These subjects have a greater than 2.5-fold increased risk for the acquisition of pneumococcal infection than do those who do not have this variant or are only heterozygous for this variant.

Immunocompetent Conditions

Studies of IPD since the introduction of PCV in 2000 have identified that an increasing proportion of cases occur in children with comorbid conditions. Children older than the age of 5 years with IPD were threefold more likely to have a comorbid condition compared with those younger than 5. Specific conditions identified by the Committee on Infectious Diseases of the American Academy of Pediatrics as indicating increased risk for pneumococcal disease include chronic lung and heart disease, diabetes mellitus, cerebrospinal fluid (CSF) leak, chronic renal failure and nephrotic syndrome (at least in part due to hypogammaglobulinemia), and cochlear implants (Table 85-1).[13] Recently presented data suggest that children with asthma and neurologic conditions including seizure disorders and muscular dystrophies are also at increased risk. The risk is further increased in children with two or more comorbidities.

Pneumococcal Serotype

A characteristic of most disease-causing strains of *S. pneumoniae* is the presence of a polysaccharide capsule. The capsular polysaccharides are composed of repeating units

TABLE 85-1 Underlying Medical Conditions That Are Indications for Pediatric Pneumococcal Immunization Listed by Risk Group

Risk Group	Condition
Immunocompetent children	Chronic heart disease*
	Chronic lung disease†
	Diabetes mellitus

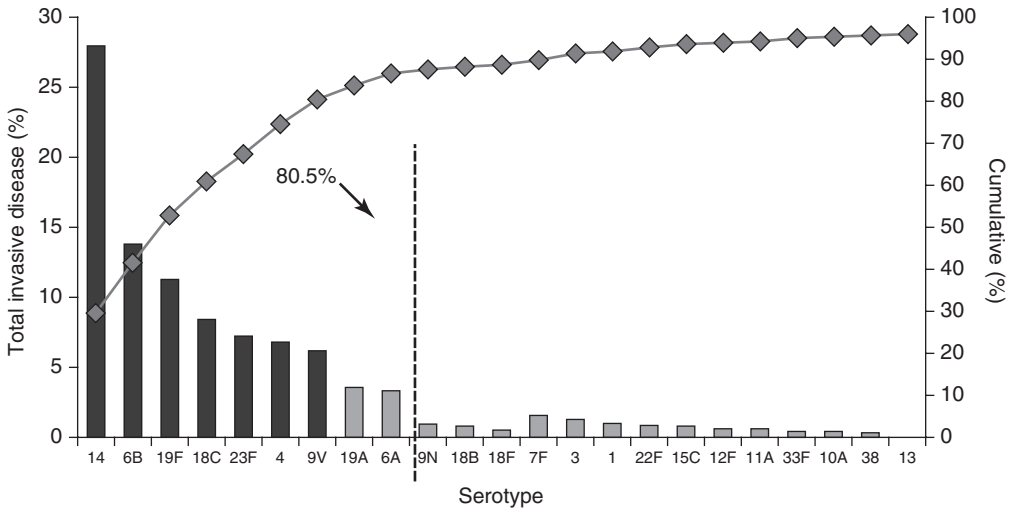
of oligosaccharides, and for most of them the exact chemical structure is known. To date, 93 distinct capsular types have been described, several of them very recently (Table 85-2). Understanding serotype distribution and characteristics is important for several reasons. First, a selected number of serotypes are responsible for the majority of disease. However the serotypes vary somewhat by geography. For example, prior to the introduction of PCV, 7 serotypes (4, 6B, 9V, 14, 18C, 19F, and 23F) accounted for 80 percent of cases of IPD in North American children (Fig. 85-10A). Globally, a larger number of serotypes, including serotypes 1, 3, and 5 must be included to account for a similar 80 percent of IPD cases (see Fig. 85-10B).[266] A significant positive association between disease and serotype has been demonstrated in children younger than 36 months, with serotypes 1, 5, and 12F associated with IPD, serotypes 1, 3, 5, 12F, 19A, and 19F with AOM, and serotype 3 and nontypeable strains with conjunctivitis. A significant negative association with IPD was demonstrated for nontypeable *S. pneumoniae* and with AOM for serotypes 6A, 6B, 15A, and nontypeable strains. Understanding the distribution of serotypes causing serious pneumococcal disease is relevant to developing vaccine strategies for prevention and estimating the impact of a vaccine that provides coverage for a limited number of serotypes. Serotype distribution also varies over time, as recent experience with serotype 1 disease in Europe demonstrated.

The serotype distribution of nasopharyngeal carriage and invasive and other pneumococcal diseases varies because not all pneumococci have the same relative risk for progressing from carriage to disease. *Invasive capacity*, the term describing the relative risk for disease occurring after a colonizing event appears to be an intrinsic property of pneumococcal strains, predominantly determined by the capsular polysaccharide. The invasive capacity for common serotypes has been computed by several investigators. Large differences among serotypes (>10-fold) have been reported and, in general, estimates of relative risk have been similar across studies. Dagan and colleagues were able to demonstrate that the capacities to cause IPD and AOM were not comparable and that differences among serotypes were blunted for AOM compared with IPD (Fig. 85-11). After the introduction of PCV, investigators in many countries have reported increases in both carriage and disease due to serotype



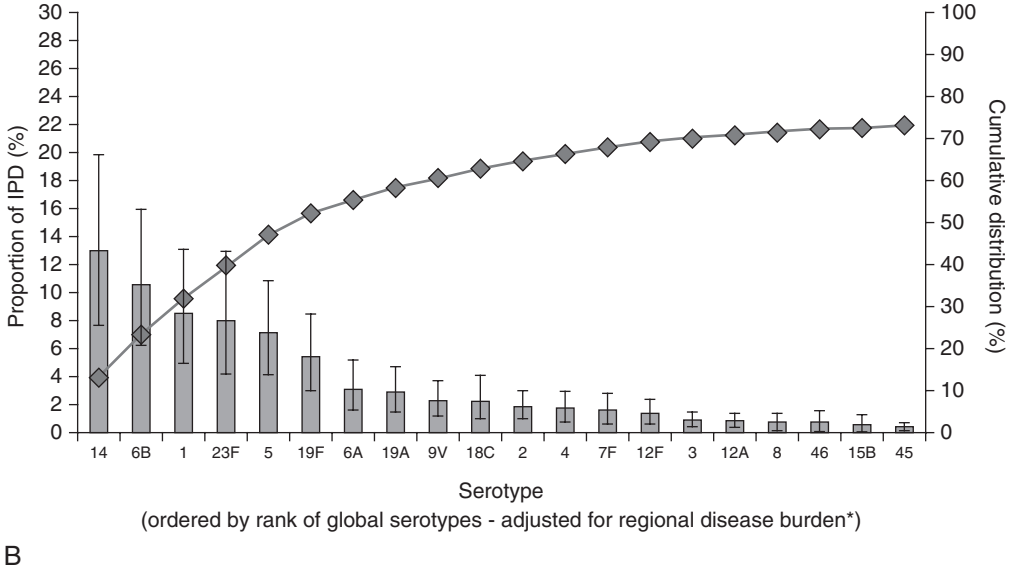


FIGURE 85-10 ■ **A,** Pneumococcal serotypes causing invasive disease in North American young children prior to PCV7. **B,** Proportion of IPD in young children due to the most common serotypes globally. Error bars indicate 95% confidence interval; cumulative line indicates proportion of IPD due to the 21 serotypes detailed. (**A,** from Hausdorff WP, Bryant J, Kloek C, et al. The contribution of specific pneumococcal serogroups to different disease manifestations: implications for conjugate vaccine formulation and use, part II. *Clin Infect Dis* 2000;**30**:122-40; **B,** from Johnson HL, Deloria-Knoll M, Levine OS, et al. Systematic evaluation of serotypes causing invasive pneumococcal disease among children under five: the pneumococcal global serotype project. *PLoS Med* 2010;**7**:e1000348.)

19A. In part, the increase in carriage resulted from intrinsic characteristics of specific clones of serotype 19A permitting them to "outcompete" other serotypes, from multidrug resistance, which allowed its persistence as a result of selective pressure from antimicrobial usage in the community, and from the lack of significant cross protection by antibodies generated in response to 19F capsular polysaccharide. It was initially hypothesized that including the capsular polysaccharide from serotype 19F in the vaccine would elicit cross-protective antibody against serotype 19A. The hypothesis was that antigenically related serotypes (those within serogroups; e.g., serotype 9A) would elicit cross-protective antibody against serotypes 9L, 9N, and 9V. However, although antibody to the 19A capsule increased after immunization with 19F as measured by enzyme-linked immunosorbent assay (ELISA), it was not sufficiently functional to prevent carriage or disease due to 19A. Proof of cross protection currently exists for antibody elicited by the 6B capsular polysaccharide, which demonstrates protection against disease and carriage due to serotype 6A. For serotype 23F, an increase in carriage of the cross-reacting serotypes 23A and 23B has been observed after immunization with PCV containing 23F capsular polysaccharide. Insufficient data are available to understand whether capsular polysaccharides elicit cross protection for other serotypes of the same serogroup. The extent of cross reactivity between types within the respective serogroups may

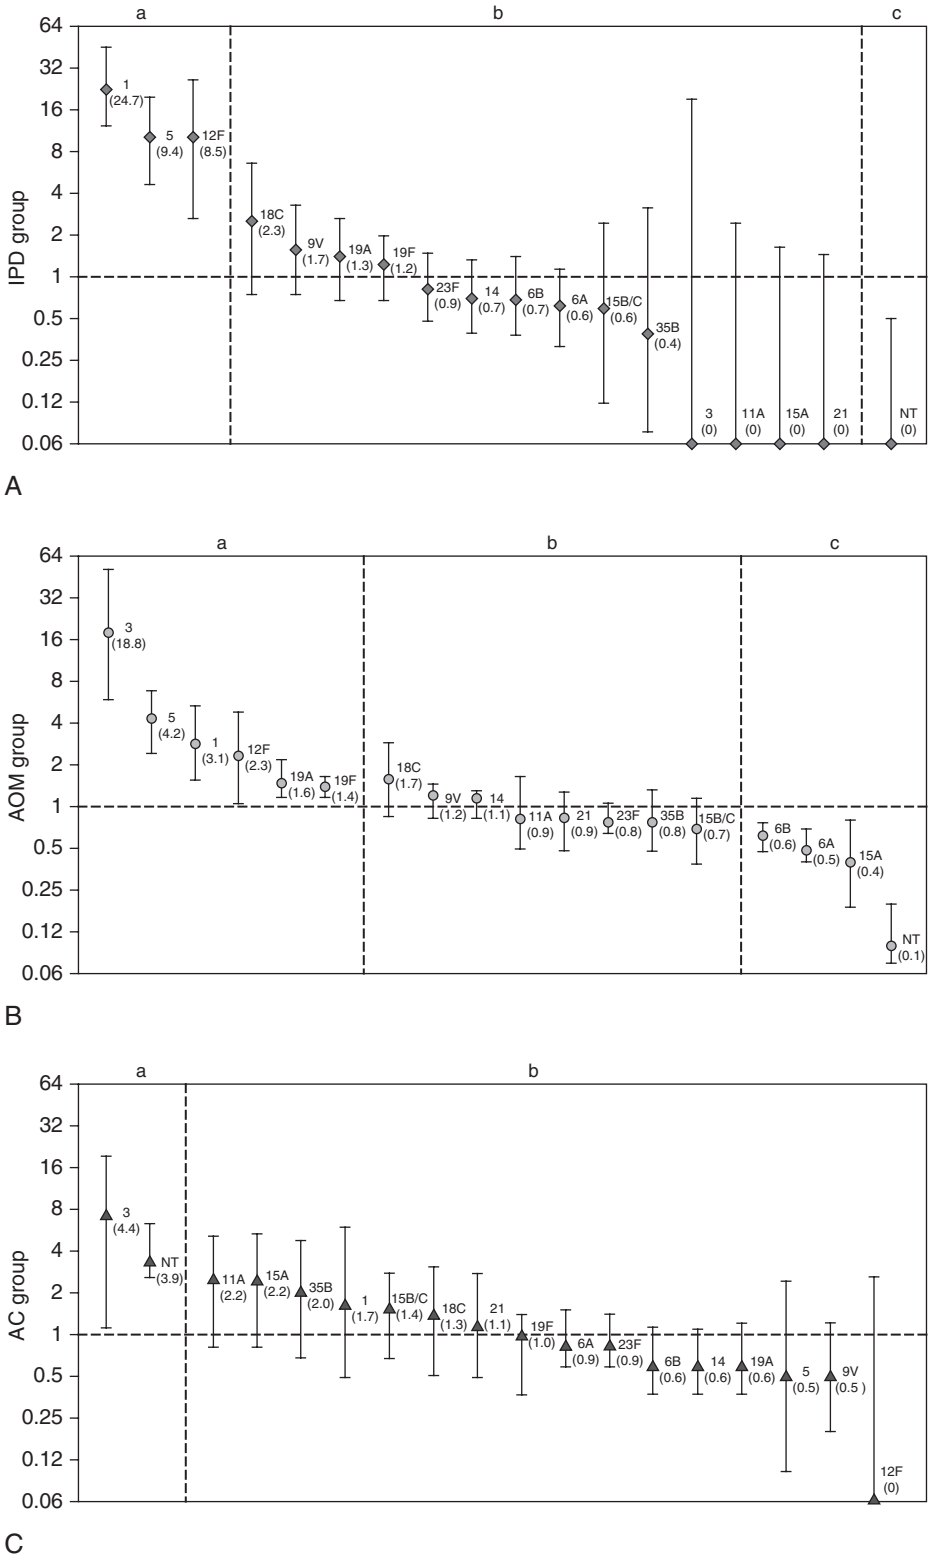

FIGURE 85-11 ■ Site-specific odds ratio for different *S. pneumoniae* serotypes for IPD, AOM, and acute conjunctivits. **A,** Serotypes with a significant positive associations. **B,** Serotypes with no significant positive or negative associations. **C,** Serotypes with a significant negative association. Site-specific disease potential of individual *Streptococcus pneumoniae* serotypes in pediatric invasive disease, acute otitis media and acute conjunctivitis. *Pediatr Infect Dis J* 2006;**25**:602-7.)

differ; for example, serotypes 6A and 6B have identical chemical composition except for one of the bonds between two sugars and are extensively cross reactive whereas types 19F and 19A are clearly less cross reactive. Poolman suggested the process of protein conjugation of the 19F polysaccharide during vaccine production altered its structure such that antibody elicited was not functional against serotype 19A strains.

Another important reason for understanding serotype differences relates to clinical disease. Different serotypes may cause specific clinical syndromes. For example, serotype 3 is associated with necrotizing pneumonia and serotype 1 is associated with empyema as well as "epidemic disease" specifically in central Africa. Serotype 1 epidemiology also differs in that it causes disease across a broader age spectrum than the usual serotypes primarily found in infants.[41,177,550] High mortalities have been associated with specific serotypes as well.[427,548,571] Serotype is also linked to antimicrobial susceptibility. Before introduction of PCV, the majority of antibiotic-resistant pneumococci were associated with five serotypes: 6B, 9V, 14, 19F, and 23F.

Other attributes beyond capsular polysaccharide also impact on clinical syndromes. Recently, differences between strains of serotype 1 in Europe and Africa have been described. In Africa, disease due to serotype 1 is often meningitis and the strain is wild type with regard to the pneumolysin produced, whereas in Europe the clinical syndromes are bacteremia and pneumonia and the strain has a mutant pneumolysin that is unable to produce hemolysis.[364,571]

PATHOGENESIS

To cause disease, pneumococci, like other extracellular bacterial pathogens, must adhere to mammalian cells, replicate in situ, be carried to and replicate in parts of the body that normally are free of them, escape phagocytosis, and damage tissue by causing inflammation or producing substances that directly damage cells and, in some cases, invade the bloodstream.[379] The vast array of virulence mechanisms available to pneumococci are countered by numerous host defense mechanisms, although some host responses facilitate infection. Even though colonization with a pneumococcal strain can progress to disease, it usually does not occur, and the development of anticapsular type-specific antibodies occurs within 30 days in older children and adults.[197,198,381,382] If organisms find their way into the eustachian tubes, sinuses, or bronchi, clearance mechanisms, chiefly ciliary action, lead to their rapid removal. After the development of humoral immunity, colonization with a strain may persist for 1 to 12 months, during which time disease may occur in contiguous sites but the host is protected from invasive disease by circulating type-specific anticapsular IgG. Loss of colonization with a strain is followed, after a variable colonization-free interval, by colonization with a different serotype. Because 93 antigenically distinct serotypes exist, this cycle of colonization accompanied by the development of humoral immunity occurs many times.

Progression of colonization to disease usually requires the combination of two events: first, acquisition of a serotype to which the host is not immune, and, second, concurrent viral respiratory tract infection, chronic damage to respiratory epithelium (e.g., from smoking or occupational exposure), allergy, or other conditions that result in the development of disease rather than just colonization.[379] Many of these concurrent conditions initiate cytokine activation of the respiratory epithelium, which facilitates increased adhesion of pneumococci to respiratory epithelial cells, as well as invasion of these cells.[321] Mechanisms by which cytokine activation facilitates pneumococcal adhesion include expression of platelet-activating factor and polymeric immunoglobulin receptor (pIgR). This combination of factors leads to a higher density of colonizing organisms and enables pneumococci to cause infection, including pneumonia, acute exacerbations of chronic bronchitis, sinusitis, otitis media, and mastoiditis, in contiguous respiratory tract sites. Adherence of *S. pneumoniae* to host cells involves an array of surface adhesin molecules such as CbpA, PspA, PspC, Hyl, Ply, PsaA and both neuraminidases (see later section on virulence factors). These proteins are involved in interactions with the host complement system (PspA), degradation of hyaluronan of the extracellular matrix (Hyl), lysis of cholesterol-containing membranes (pneumolysin), and binding of metals (divalent cations) such as manganese or zinc (PsaA), followed by their transport inside the cytoplasm of pneumococci. Additionally, transepithelial and transendothelial transport of organisms into the bloodstream results in bacteremia and subsequent transport across other epithelial cells leads to infection of noncontiguous sites such as the leptomeninges, peritoneum, and joint spaces. Such infection occurs in nonimmune hosts by virtue of the fact that pneumococci are able to escape ingestion and killing by host phagocytic cells in the absence of type-specific antibody because the capsule inhibits phagocytosis. *S. pneumoniae* produces few toxins and largely causes disease by its capacity to replicate in host tissues and generate an intense inflammatory response. Cell wall teichoic acid (TA) and peptidoglycan stimulate the production of cytokines (interleukin [IL]-1, IL-6, IL-8, and tumor necrosis factor [TNF]) and activate complement by the alternative pathway. The polysaccharide capsule also activates the alternative complement pathway in vitro. Such activation is associated with the release of C5a, a potent attractant for polymorphonuclear neutrophils. The classic complement pathway also is activated by antibody to cell wall polysaccharides in the absence of anticapsular antibody, and an intense inflammatory response fueled by vigorous activation of both the alternative and classical complement pathways accompanies pneumococcal infection of an immunologically naïve host.[379] The disease process is largely a result of this inflammation, and its severity is in direct proportion to its intensity. Pneumolysin also is associated with the severity of disease, and injection of pneumolysin into rat lung causes all the histologic findings of pneumonia, whereas immunization of mice with pneumolysin before infection or challenge with pneumolysin knockout pneumococci is associated with a significant reduction in virulence.[40,155] Mitchell reports that

some nonmeningitis strains of serotype 1 have a mutant nonhemolytic pneumolysin.[364] As discussed later in the section on virulence factors, there are numerous other factors that contribute to the ability of pneumococcal strains to cause disease and regulate severity.

A 2006 study evaluated the association of serotype with pneumococcal disease among 189 isolates from blood or CSF, 3200 isolates from middle ear fluid, and 348 isolates from the conjunctiva of children aged younger than 36 months with pneumococcal infection. A positive association with IPD was demonstrated for serotypes 1, 5, and 12F; with AOM for serotypes 1, 3, 5, 12F, 19A, and 19F; and with acute conjunctivitis for serotype 3 and nontypeable *S. pneumoniae*.[488] Although pneumococci most commonly cause bacteremia, otitis media, pneumonia, and meningitis, they can produce disease in virtually any organ. Before the advent of immunotherapy and chemotherapy, such "unusual" infections were relatively common. Today, they are less so. Survival of a patient with a pneumococcal disease depends on numerous variables, including the site of infection, the underlying disease, and the patient's age. Before the advent of chemotherapy, pneumococcal meningitis was almost universally fatal, whereas pneumococcal pneumonia killed approximately 25 percent of hospitalized patients. Austrian and Gold, in 1964, dramatically illustrated the role of age and underlying disease when their survey of mortality associated with bacteremic pneumococcal pneumonia destroyed the complacency produced by the use of antimicrobial agents.[34] The aged and infirm were likely to die despite receiving immediate and appropriate therapy with penicillin. Today, normal children living in industrialized countries rarely die of pneumococcal disease; thus, the prognosis must be related to the likelihood of permanent sequelae occurring. Pneumococci do not usually cause necrosis in pulmonary tissue, and survivors rapidly regain normal pulmonary function.[261] Many children recovering from pneumococcal meningitis are found to have neurologic sequelae. Some investigators suggest that the first attack of pneumococcal otitis media in some way predisposes the individual to subsequent attacks of otitis media.[237] Before the availability of antimicrobial agents, recovery of a patient with pneumococcal pneumonia depended on the development of type-specific antibody. Although serum and white blood cells (WBCs) from nonimmune children kill pneumococci, probably by activation of the alternative complement pathway, they do so slowly. The importance of this pathway is illustrated best by the inability of children with sickle-cell disease to handle pneumococcal infection.[128,268,415] These children and others with asplenia may die rapidly despite the administration of prompt, vigorous therapy.[271,285,481]

MICROBIOLOGY

Structure

Pneumococcal cells are surrounded by a trilamellar, lipopolysaccharide, cytoplasmic membrane that has two electron-dense bands, each 25 to 30 Å wide. A cell wall surrounding the plasma membrane has two bands-an inner 30- to 40-Å-wide band and an outer 60- to 80-Å-wide band. Numerous bridges connect the cell wall and the plasma membrane. The polysaccharide capsule covers the cell wall in encapsulated strains and is seen as a wider, less-structured band.[534] A schematic representation of the major structural components and selected cell wall components is shown in Figure 85-12.

Cell Wall Structure

The predominant structural components of the pneumococcal cell wall are peptidoglycan, TA, lipoteichoic acid (LTA), and several choline-bound proteins. Choline is a lipid that is an essential growth factor for *S. pneumoniae*.

Peptidoglycan. Peptidoglycan, which accounts for approximately half of the cell wall mass, is a cell wall polymer linked by stem peptides to form a complex, three-dimensional structure.[484] Stem peptides are formed when transpeptidases (also known as *penicillin-binding proteins* [PBPs]) link pentapeptide chains into linear stem peptides in penicillin-susceptible strains. However, in non-penicillin-susceptible strains, branched and other variant stem peptides are produced.

Lipoteichoic Acid. LTA also is known as *pneumococcal Forssman (F) antigen*. The LTA of pneumococci possesses identical repeat and chain structures linked to a cell membrane glycolipid that anchors LTA to the cell.[161,162] Phosphocholine is attached to saccharide residues. PspA and other proteins (see later discussion) also are attached to choline residues on LTA.

Teichoic Acid. TA, also known as *pneumococcal C polysaccharide*, has a chain structure similar to that of LTA, except that the saccharide differs. TA chains are attached to the cell wall peptidoglycan. Some phosphocholine residues of both LTA and TA are expressed on the cell wall surface, where they are thought to serve three functions: (1) activation of the pneumococcal autolysin (LytA) enzyme, which is responsible for the autolysis of pneumococci; (2) binding of the choline-binding domain of LytA to choline on TA, which may regulate the activity of LytA; and (3) a function associated with transformability (choline-deficient cells lack transformability).[193,262]

Surface Proteins. Pneumococci have several surface proteins, with the five most important being *pneumococcal surface protein A* (PspA), *pneumococcal surface adhesin A* (PsaA), *choline-binding protein A* (CbpA), *hyaluronate lyase* (Hyl), and *pilin protein* (RrgB).

PspA is a cell wall protein with a molecular size of 67 to 99 kDa that is bound to TA and LTA by phosphocholine links.[262] This protein extends through the cell wall and capsule to the surface of the organism.[594] PspA exists in various antigenic forms, and epitopes within one PspA molecule can recombine into different types.[74] However, PspA variants usually are sufficiently cross reactive that immunization with one PspA serotype elicits immunity to other PspA serotypes.

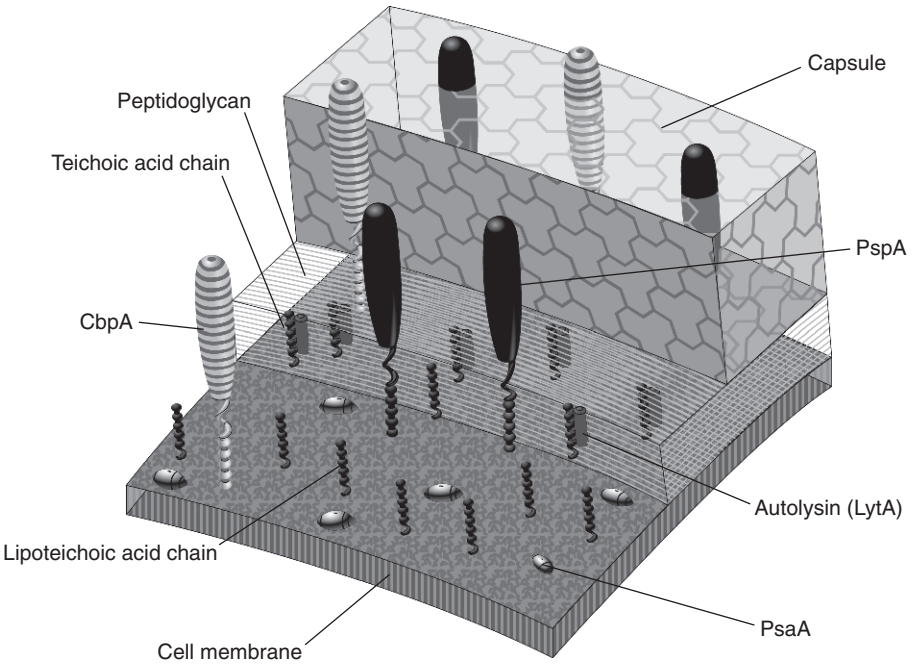

FIGURE 85-12 ■ Schematic three-dimensional representation of the major structural components of the cell membrane, cell wall, and capsule of *Streptococcus pneumoniae*. The locations of selected major virulence factors of the organism are shown as well. Chains of lipoteichoic acid are attached to cell membrane glycolipid, whereas surface proteins, such as PspA and CbpA, in turn are attached to the lipoteichoic acid chains via phosphocholine links. PsaA is found on the outer surface of the cell membrane. (Copyright Michael R. Jacobs, used with permission.)

PsaA is a 37-kDa surface protein thought to be anchored to the cell membrane and associated with magnesium and zinc transport.[129] It appears to be a lipoprotein and is common to virtually all *S. pneumoniae* isolates.[440] Considerable variation in the amino acid sequences of PsaA from different strains has been detected.[413] The relationship of this protein to other cell wall components has not been determined.[523]

CbpA is a protein similar to PspA and has a mass of 75 kDa. It is an adhesin involved in the adherence of pneumococci to cytokine-activated human cells.[458] Several other choline-binding proteins also have been identified.

Hyl is a hyaluronidase that results in breakdown of the hyaluronan and chondroitin sulfate present in the extracellular matrix of human tissues.[458]

Pilin protein (RrgB) is present on the surface of virulent pneumococci in the form of a pilus shaft, which is a long, thin proteinaceous filament extending from the cell wall that aids bacterial colonization in the nasopharynx through epithelial cell binding.[412] It has a large adhesive pilin at the tip, a polymeric shaft, and a smaller cell wall anchor and is composed of four immunoglobulin-like domains. Isopeptide bond formation in the N-terminal domains, which provides the covalent linkage to the next pilin subunit in the shaft, appears to take place only on assembly of the pili.

Capsule

The capsule of pneumococci consists of polysaccharides that vary in the make-up of monosaccharides, the sequence of monosaccharides in polysaccharides, the linkage of monosaccharides to each other, and the presence of nonsaccharide components.[156] Currently, 93 serotypes consisting of 25 individual serotypes and 68 serotypes grouped into 21 serogroups are known (Table 85-2). Each serotype has a specific capsular structure, and serotypes within a serogroup often have the same oligosaccharide sequences linked differently. The capsular structure of many serotypes has been determined.[351]

Several epidemic clones have been shown to have different serotypes, and extensive genetic changes involving the replacement of entire cassettes of genes related to capsule production are required for capsular switching to take place.[5]

Genome

The complete pneumococcal genome has been mapped. The genome has been estimated to be 2.0 to 2.1 megabases (Mb), approximately half that of *Escherichia coli*.[43,131] The locations of more than 100 genes, including 20 tRNA synthetase and 20 ribosomal protein genes, have been mapped. Genes involved in cell wall synthesis also have been identified. *S. pneumoniae* is a naturally transformable bacterium, which means that it is able to take up single-stranded DNA from its environment and incorporate this exogenous DNA into its genome. This process is known as *transformational recombination*.[373,505] Recombination is a powerful means of genome evolution and provides a great degree of genome flexibility to this organism. Transformation occurs only at high cell densities (10^5 to 10^8 colony-forming units/mL), and a peptide

pheromone quorum-sensing signal called *activator* or *competence factor* is required.[436] This factor also is termed *competence-stimulating peptide.*[508] The genes associated with capsule synthesis have been characterized for several serotypes as well. The complete nucleotide sequence of many of these genes of several *S. pneumoniae* serotypes has been determined.[27,172,370,569]

Virulence Factors

Animal models of pneumococcal infection have provided considerable insight into the pathogenesis of disease and the association of virulence factors with disease. However, the pneumococcus is primarily a human pathogen and the host defenses of animal models can vary significantly from those in humans. For example, pneumococci adhere to human but not to rabbit polymeric immunoglobulin receptor (pIgR).[49,601] Additionally, virulence in mice varies considerably with the strain of pneumococcus: pneumococci belonging to serogroups 6, 14, 19, and 23 rarely are virulent in mice, whereas serotypes 1, 2, and 3 usually are virulent.[73,601] Virulence also may vary according to the mouse strain.*

Some serotypes can be virulent to one species of animal but not to others. An example is serotype 19F, which rarely is virulent in mice[36] but is highly virulent in guinea pigs.[32] In addition, penicillin resistance appears to be linked to decreased virulence by virtue of the fact that virulence of isogenic mutants of a virulent, penicillin-susceptible strain was reduced significantly when transformed into a penicillin-resistant strain with an abnormal *pbp2x* gene.[445] Therefore, many animal models of pneumococcal virulence may not be representative of virulence in humans or representative of all pneumococcal serotypes or antimicrobial-resistant strains.

Although the polysaccharide capsule has been recognized as the major determinant of virulence, relatively little is known about the molecular basis of the pathogenesis of pneumococcal disease. A library of 1786 pneumococcal mutants created by insertion-duplication mutagenesis was analyzed for their ability to survive and replicate in murine models of pneumonia and bacteremia.[309] One hundred eighty-six mutant strains exhibited attenuated virulence; 56 of these strains were genetically characterized, and genomic DNA inserts were sequenced and subjected to database searches. Most of the insertions were in probable operons, but no pathogenicity islands were found. Forty-two novel virulence loci were identified. Five strains showed mutations in genes involved in gene regulation, cation transport, or stress tolerance; the virulence of these strains was shown to be highly attenuated in a murine respiratory tract infection model. Additional experiments also suggest that induction of competence for genetic transformation has a role in virulence.[309] This approach has revealed several previously unrecognized genes required for virulence.

A similar genomic approach was used to look for genes coding for surface-localized proteins that could be targets for protective humoral immunity. By exploiting the whole-genome sequence of *S. pneumoniae*, researchers found 130 open-reading frames encoding proteins with secretion motifs or similarity to predicted virulence factors.[413] Mice were immunized with 108 of these proteins, and 6 proteins conferred protection against disseminated pneumococcal infection. Each of the protective antigens showed broad strain distribution and immunogenicity in human infections. Some of these proteins have been identified as LytB, LytC, and a cell wall–anchored serine protease. Another genomic-based study used a genomic expression library of *S. pneumoniae* screened with convalescent-phase serum for immunoreactive proteins.[605] Six known and 17 unknown pneumococcal proteins were detected. Five of the known proteins, including PspA and SpsA (CbpA), were surface-located virulence factors, and 8 of the unknown proteins were putative membrane proteins. Use of these genomic approaches for the identification of novel microbial targets to elicit a protective immune response has been validated, and these new antigens may play roles in the development of improved vaccines against *S. pneumoniae.*

Capsule

The capsule is the major determinant of virulence in pneumococci. It prevents phagocytosis by polymorphonuclear leukocytes (PMNs) and macrophages, thereby allowing unrestricted extracellular multiplication of the organism. Because the pneumococcus has 93 antigenically distinct serotypes, production of anticapsular antibody in response to one serotype provides protection against only that serotype or serogroup, whereas nonencapsulated strains are considerably less virulent.[379] The importance of the capsule as a virulence factor is emphasized by the fact that protection from pneumococcal infection can be achieved by capsular-specific antibodies. Despite the large number of additional virulence factors, the capsule remains the single most important determinant of virulence in avoiding host defenses after the epithelial barriers have been breached. Other virulence factors are important in breaching host defenses such as epithelial barriers.

Neuraminidases

Neuraminidases are enzymes that cleave terminal sialic acid residues from glycolipids, glycoproteins, and oligosaccharides on eukaryotic cell surfaces; such cleavage may unmask cell surface receptors for pneumococcal adhesins.[413] The neuraminidase NanA has been implicated in the ability of *S. pneumoniae* to colonize and persist in the nasopharynx and middle ear.[535] A second neuraminidase, NanB, has much weaker activity than NanA does but exhibits optimal activity at pH 5, whereas NanA is most active at pH 7.[413]

Pneumolysin

Pneumolysin is a 53-kDa cytoplasmic protein produced by all pneumococci. It is essential for the initial binding to membrane cholesterol and the interaction leading to subsequent membrane damage.[37]

*References 1, 32, 36, 301, 445, 530.

Functions of pneumolysin include the following:

1. Pore formation in host epithelial cell membranes. Pneumolysin binds to cholesterol in host epithelial cell membranes, where oligomers of pneumolysin molecules assemble to form 35- to 45-nm pores in the cell membrane, which results in lysis of the targeted cell. Pneumolysin is, therefore, cytotoxic to epithelial cells, and it also slows ciliary beating of bronchial epithelial cells and disrupts the tight junctions between epithelial cells. In addition, pneumolysin disrupts alveolar epithelial cells and the alveolar-capillary boundary, thereby facilitating entry of pneumococci into the bloodstream and through the blood-brain barrier.[183,606]
2. Effects on phagocytic and immune cell function. Pneumolysin attracts neutrophils in the early phases of disease and lymphocytes at a later stage.
3. Direct activation of the complement system. Expression of pneumolysin by pneumococci reduces serum complement levels and serum opsonic activity.[10]
4. Promotion of nitric oxide (NO) production by macrophages. NO is produced by an inducible NO synthase (iNOS) during inflammation as an essential element of antimicrobial defense, but it also can contribute to host-induced tissue damage.[71]

Surface-Located Choline-Binding Proteins

The virulence of members of the choline-binding protein (Cbp) family and two recently described cell wall hydrolases, LytB and LytC, has been characterized.[193] Cbp-, LytB-, and LytC-deficient mutants show significantly reduced colonization of the nasopharynx. The following proteins of the Cbp family and their virulence mechanisms have been described:

1. PspA is a serologically variable protein that has undergone extensive recombination.[233] It is thought to exert its virulence function in systemic infection by interfering with deposition of the complement component C3b onto pneumococci or by blocking recruitment of the alternative pathway, thereby reducing the effectiveness of complement receptor-mediated pathways of clearance.[539] PspA has been shown to bind to lactoferrin, an iron-sequestering glycoprotein found in mucosal secretions, when the level of free extracellular iron is not sufficient for the growth of pneumococci. This binding is thought to overcome the iron limitation at mucosal surfaces and might represent a potential virulence mechanism for colonization of mucosal surfaces.[212]
2. CbpA, or SpsA, is a surface protein adhesin that acts as a bridging element between pneumococci and host-cell glycoconjugates on cytokine-activated host cells.[213] This process is thought to be associated with change from nasopharyngeal colonization to invasion of epithelial and endothelial cells.[458] One mechanism by which this process occurs, wherein CbpA binds to the pIgR of human epithelial cells, has been described.[599] The pneumococcus co-opts the IgA transcytosis machinery and gains entry into and across airway epithelial cells. This process is a novel example of a pathogen co-opting the transcytosis machinery to promote translocation across a mucosal barrier.[273]
3. PsaA is a surface protein that also is associated with virulence via adhesion to epithelial cells.
4. Pneumococcal histidine-containing protein A (PhpA) is a 20-kDa protein with putative proteolytic activity against the human complement component C3. PhpA is a potential candidate for use as a vaccine against systemic pneumococcal disease and otitis media.[601]
5. The pneumococcal histidine triad (Pht) proteins PhtA, PhtB, PhtD, and PhtE constitute a novel family of homologous surface proteins associated with virulence; they are also potential vaccine candidates.[9] Although antibodies targeting PhtA, PhtB, or PhtD are protective, the function of these proteins remains unknown. The number of histidine and tyrosine residues in these proteins suggests that they may be involved in metal or nucleoside binding.

Phase Variation

Phase variation in the colonial opacity of *S. pneumoniae* has been implicated as a factor in bacterial adherence, colonization, and invasion.[572] On clear media, colonies can appear as opaque or translucent when viewed under magnification with oblique, transmitted light. All strains of *S. pneumoniae* are thought to be capable of phase variation. Opaque colonies are less likely to autolyze, contain less TA but more PspA in their cell walls, and colonize the nasopharynx poorly in animal models but are more virulent when inoculated into sterile sites. Conversely, translucent colonies are more likely to autolyze, contain more TA but less PspA in their cell walls, and colonize the nasopharynx well but are less virulent when inoculated into sterile sites. Translucent colonies become umbilicated as a result of autolysis, whereas opaque colonies remain dome shaped.

Phosphorylcholine Esterase

This enzyme has activity that removes phosphorylcholine residues from cell wall TA and LTA.[557]

Inactivation of the gene encoding for the enzyme in pneumococcal strains caused a change in colony morphology from translucent (colonizing) to opaque (virulent) and a striking increase in virulence in the intraperitoneal mouse model. Phosphorylcholine esterase therefore appears to be a regulatory element involved in the interaction of *S. pneumoniae* with its host.

Pneumococcal Autolysin

Pneumococcal autolysin (LytA) is a 36-kDa cell wall protein attached to choline residues on TA and LTA. It is associated with unlinking of cell wall glycan from stem peptides during cell remodeling and division. Autolysin initially was considered to be a significant virulence factor, but more recent work has shown that it plays only a minor role and that immunization with autolysin does not provide protection.[413]

Cell Wall Stem Peptides

The peptidoglycan of gram-positive bacteria triggers the release of cytokines from peripheral blood mononuclear cells.[345] However, 100 to 1000 times more gram-positive peptidoglycan than gram-negative lipopolysaccharide endotoxin is required to release the same amount of cytokine. Simple stem peptides were 10-fold less active than was undigested peptidoglycan in stimulating TNF. In contrast, complex branched peptides such as tripeptides were at least 100-fold more potent than was the native material. These complex branched peptides represented 2 percent or less of the total material, but their activity in stimulating TNF was almost equal to that of endotoxin.

Iron Transport

The availability of iron is a major requirement for the growth and survival of many organisms, including *S. pneumoniae*. Two *S. pneumoniae* genetic loci, *pit1* and *pit2*, which encode homologs of ABC iron transporters, are required for uptake of iron by this organism.[78] Virulence in mouse models of pulmonary and systemic infection is attenuated moderately with a *pit2*-disrupted strain and attenuated strongly with a *pit1/pit2*-disrupted strain.

IgA Protease

IgA proteases belong to a family of proteins used by a diverse group of bacteria, including *S. pneumoniae*, for colonization and invasion. IgA1 protease allows bacteria to cleave human IgA1 in the hinge region. The exact role of these enzymes in bacterial pathogenesis is not understood completely, but they are important in bacterial colonization of mucosal membranes in the presence of secretory IgA antibodies by causing local IgA deficiency.[281] The IgA protease genes of *S. pneumoniae* and *Streptococcus mitis* show extensive polymorphism, which results in enzymes with considerable antigenic diversity.[429]

Phosphoglucomutase

Phosphoglucomutase is an enzyme that is necessary in one of the early steps in capsular polysaccharide synthesis, and *S. pneumoniae* mutants lacking this enzyme do not produce a capsule and are avirulent in immunocompetent but not in immunosuppressed mice.[214] Other metabolic pathways also are thought to be affected by this enzyme.

Free Oxygen Radicals

Release of free oxygen radicals has been implicated in the pathogenesis of otitis media by *S. pneumoniae*, and antibiotic killing of bacteria leads to the release of further free oxygen radicals, which results in tissue damage despite the administration of appropriate antibiotic therapy.[521] Reactive oxygen intermediates also mediate brain injury in bacterial meningitis.[30,333]

NADH Oxidase

Reduced nicotinamide adenine dinucleotide (NADH) oxidase has been shown to be a virulence factor necessary for *S. pneumoniae* infection. The basis of NADH oxidase as a virulence factor is the conversion of O_2 to H_2O. If O_2 is not reduced fully, it can form superoxide anion (O_2^-) and hydrogen peroxide (H_2O_2), both of which can be toxic to cells.[595]

Pyruvate Oxidase

Pyruvate oxidase decarboxylates pyruvate to acetyl phosphate plus H_2O_2 and CO_2 and appears to be associated with regulation of the multiple adhesive properties of pneumococci.[504] A pneumococcal mutant lacking the gene encoding pyruvate kinase showed a greater than 70 percent loss of the ability to attach to all cell types.

Plasminogen Binding and Penetration of the Basement Membrane

Binding of plasminogen plus penetration of the basement membrane is thought to be an essential step in the pathogenesis of bacterial meningitis.[137] Most strains adhere to reconstituted basement membrane, as well as to its purified laminin and collagen IV components, and to bound plasminogen. Penetration of the basement membrane was achieved within 3 to 4 hours in the presence of plasminogen, whereas without plasminogen no penetration occurred.

Hyaluronidase

Virtually all pneumococcal strains produce the enzyme hyaluronidase, a 107-kDa protein. Models used to simulate human meningitis generally involve the direct intracerebral route of infection. However, intranasal inoculation would provide a more realistic model, and this was achieved by intranasal administration of *S. pneumoniae* with hyaluronidase. This model induced meningitis in 50 percent of inoculated mice, whereas meningitis did not develop in any of the mice inoculated without hyaluronidase. Hyaluronidase was found to facilitate pneumococcal invasion of the bloodstream after colonization of the upper respiratory tract. This murine model mimics important features of human disease, which allows the model to be used to study issues related to the pathophysiology and treatment of pneumococcal meningitis.[604]

Peptidoglycan N-Acetylglucosamine Deacetylase A

The glucosamine and muramic acid residues of the pneumococcal cell wall traditionally are regarded as being *N*-acetylated. However, more than 80 percent of the glucosamine and 10 percent of the muramic acid residues have been shown to be deacetylated, thereby explaining the resistance of peptidoglycan to the hydrolytic action of lysozyme, a muramidase that cleaves the glycan backbone.[556] A gene that encodes for peptidoglycan *N*-acetylglucosamine deacetylase A has been identified. This gene may, therefore, contribute to pneumococcal virulence by providing protection against host lysozyme, which is known to accumulate in high concentration at sites of infection.

Phages

Whereas transformation is recognized as occurring in pneumococci, another mechanism of DNA transfer in pneumococci is transduction of DNA carried by bacteriophages (lysogeny). A high proportion (76% of 791 isolates) of clinical isolates of pneumococci were found to carry multiple copies of LytA, thus indicating the widespread occurrence of lysogeny in pneumococci.[437] The LytA hybridization pattern of a strain has been found to be stable during extensive serial culturing; it is specific for the clonal type of the strain and can be used as a molecular epidemiologic marker. In addition, phage DNA integrated into the pneumococcal genome acts as an integrase to facilitate the introduction of foreign genes into the pneumococcal chromosome.[184]

Tolerance

The ability of *S. pneumoniae* to escape lysis and killing by vancomycin and penicillin, a property termed *tolerance*, has been described.[228] Among 116 clinical isolates of pneumococci, 3 percent and 8 percent were tolerant to vancomycin and penicillin, respectively. Tolerance may contribute to treatment failure, particularly in meningitis, in which bactericidal activity is critical for eradication. A vancomycin- and cephalosporin-tolerant strain of *S. pneumoniae*, the Tupelo strain, has been isolated from the CSF of a patient in whom recrudescence of meningitis developed despite treatment with vancomycin and a third-generation cephalosporin.[355] The defect leading to tolerance in this strain involves the control pathway for triggering of autolysis via a mutated CiaH histidine kinase.[374] A frameshift mutation in the *lytA* gene encoding the main pneumococcal autolysin was associated with vancomycin tolerance in another strain.[374]

Viral Respiratory Tract Infections

The role of viral respiratory tract infection in predisposing the host to secondary bacterial infection, including pneumonia, empyema, and lung abscess, is well recognized.[321] The lungs of immunocompetent mice infected with influenza A virus on day 1 and *S. pneumoniae* on day 8 demonstrate greater *S. pneumoniae* colony counts, more extensive neutrophil infiltration, and higher lung levels of IL-1β and TNF-α after exposure to *S. pneumoniae* than do the lungs of control mice not preinfected with influenza virus.[321] Influenza A virus facilitates *S. pneumoniae* transmission and disease, with secondary bacterial pneumonia representing an important cause of excess mortality during both influenza epidemics and pandemics.[11,127] This lethal synergism between influenza virus and *S. pneumoniae* was first suggested by studies performed on samples collected during autopsy from victims of the 1918 influenza pandemic and recently confirmed by data collected during the 2009 A/H1N1v influenza pandemic.

Diagnostic Microbiology

S. pneumoniae is a gram-positive coccus that replicates in pairs and chains in liquid medium. The shape of the individual organism is a lanceolate coccus that usually occurs in pairs with the long axis forming a straight line. Elongated or pointed forms are commonly found.

Isolation

Pneumococci are cultured readily on blood and chocolate agar media, as well as in suitable liquid culture media for isolation from blood. Isolates are facultative anaerobes, and most strains require atmospheric enrichment with 5 to 10 percent CO_2 for primary isolation[33]; occasional strains are strict anaerobes. Strains can be adapted for growth without CO_2 supplementation by repeated subculture. Detection of nasopharyngeal carriage of pneumococci is a problem because of the presence of other flora; the use of antimicrobial-containing media, such as blood agar supplemented with gentamicin (5 μg/mL), has led to improvements in isolation of pneumococci, particularly resistant strains.[416,434] However, the sensitivity of current in vitro methods is poor in comparison to the sensitivity of mouse inoculation, although not all serotypes are virulent in mice.[232,293]

Identification

Pneumococci usually are identified readily by standard features such as colonial morphology, α-hemolysis, negative catalase reaction, optochin susceptibility, bile solubility, and specific reactions with antisera to capsular polysaccharides.[252] *S. pneumoniae* produces an autolytic intracellular enzyme, LytA, that causes the organism to autolyze rapidly when grown on artificial media. Bile salts and optochin accelerate this natural autolytic process by combining with the pneumococcal cell and activating its autolysin. Strains with atypical features, such as rounded rather than flat or concentrically ringed colonies, optochin resistance, or lack of capsules, do occur and can result in misidentification of such strains as viridans streptococci. Atypical strains are more likely to be encountered from normal flora sites and with

penicillin-resistant strains. Molecular methods for identification of pneumococci include polymerase chain reaction (PCR) detection of *ply* and *psaA* genes, multilocus sequence typing (MLST), 16S rRNA gene sequencing, and pyrosequencing. The presence of *psaA* is useful in distinguishing between atypical pneumococci and other streptococcal species.[252]

Strains with optochin zones greater than 14 mm can be identified presumptively as pneumococci, strains with 7- to 14-mm zones require confirmation by bile solubility, and strains with no zone usually are not *S. pneumoniae*. However, incubation in carbon dioxide has been recognized for a long time as decreasing the size of the zone around optochin disks, and incubation in room air generally results in an increase in zone size if the strain is a pneumococcus or a decrease if the strain is a member of the viridans group of streptococci.[435] Optochin-resistant variants of pneumococci can occur and usually are seen as a subpopulation within the zone of inhibition of an optochin disk, and optochin-resistant mutants can be selected by passage of strains in the presence of optochin.[378] Strains with equivocal optochin zones or atypical colonial morphology can be tested for bile solubility, either directly by placing a drop of bile salt solution (10% sodium deoxycholate) onto colonies and observing for lysis of the colonies or by suspension of organisms in a bile salt solution with a bile salt-free control. Care must be taken in the tube bile solubility test to avoid obtaining false-positive results, which can be caused by the organism suspension being too light or by organisms being suspended in broth rather than saline.[252]

Matrix-assisted laser desorption ionization-time-of-flight mass spectrometry (MALDI-TOF MS) fingerprinting systems are increasingly being used for bacterial identification in the routine diagnostic microbiology laboratory but may not adequately differentiate pneumococci from species within the *Streptococcus mitis* group, which includes *S. pneumoniae*. A comparative analysis of MALDI-TOF spectra of several species from the *S. mitis* group suggests that it is possible to distinguish different species of the *S. mitis* group by close analysis of their mass peak profiles.[574]

Identification of the capsular polysaccharide serotype or serogroup also is useful in characterizing strains and confirming the identity of problem strains. Such identification is performed by the capsular swelling technique, in which equal volumes of an organism suspension, 0.3 percent methylene blue dye solution, and antiserum are mixed on a glass slide, covered with a coverslip, and read at 1000× magnification by phase-contrast microscopy. Alternatively, organism suspensions can be dried on slides and antiserum and methylene blue dye solution mixed on a coverslip, which then is placed on the slide. The polysaccharide capsule of the pneumococcal organism binds with type-specific antiserum, and organisms can be seen to clump or agglutinate; the resulting change in the refractive index of antibody-coated capsule causes the capsule to appear swollen. Antisera to each serotype or serogroup and factoring antisera to subtype serogroups are available from Statens Serum Institut, Copenhagen, Denmark.[227] The numbering system for pneumococcal serotypes is shown in Table 85-2.

Currently, 93 serotypes have been identified and are divided into 25 individual serotypes and 21 serogroups in the Danish classification, which now is used universally. Most serotypes have one antigenic determinant, whereas serogroups have one or more antigenic determinants common to the group and one or more determinants unique to each serotype. Serotypes within a serogroup usually are identified by the serogroup number followed by a letter indicating the serotype to which a strain belongs. Except for serogroups 6 and 9, the letters are F for the first subtype, followed by A, B, and so on. Each serogroup contains two to six related types, and the 21 serogroups currently include over 67 individual subtypes. Serotype numbers 26 and 30 are not in use. Serotype 2, an extremely uncommon pneumococcal serotype, has recently been detected as the leading pneumococcal serotype (20% of 221 cases) in childhood meningitis in Bangladesh.[465] These serotype 2 strains had three closely related pulsed-field gel electrophoresis types.

Omniserum containing antibodies to all serotypes is available and can be used to confirm the identity of isolates as pneumococci. Because many serotypes or serogroups are included in this reagent, reactions may not always be optimal and usually are stronger in pool or monovalent reagents. Nine antiserum pools classified from A to I, each containing four to seven serotypes or serogroups, also are available and can be used to identify strains in a group of serotypes before individual serotype or serogroup reagents are tested. Other methods of capsular typing, such as latex agglutination, coagglutination, and capillary precipitation, can be used, but these methods are not available commercially. The ability of a PCR method to identify the capsular serotype of pneumococci has been developed on the basis of polymorphisms in two genes common to the different capsule loci.[312] PCR analysis holds promise as a noncultural method for determining serotype.

Detection of Clonality

In addition to phenotypic features, such as serotype and antimicrobial resistance markers, various DNA fingerprint methods for epidemiologic typing of *S. pneumoniae* have been applied. The currently recognized reference method is multilocus sequence typing (MLST), in which 450 bp fragments of seven housekeeping loci are determined. The combination of alleles at these seven loci provided a sequence type (ST), and the relatedness between isolates is obtained by constructing a dendrogram from the matrix of pairwise differences between STs.[136,144,344] Other typing methods include ribotyping, BOX fingerprinting with the BOX repetitive sequence of *S. pneumoniae* used as a DNA probe, PCR fingerprinting with a primer homologous to the enterobacterial repetitive intergenic consensus sequence, pulsed-field gel electrophoresis of large DNA fragments digested by restriction enzymes, and detection of polymorphic DNA sequences for a multiple-locus variable-number tandem-repeat analysis (MLVA).[229,356]

Diagnosis of Pneumococcal Disease

Definitive diagnosis of pneumococcal infection is based on recovery of pneumococci from the site of infection or documentation of pneumococcal bacteremia, whereas presumptive diagnosis is based on detection of pneumococcal cellular components, such as capsular polysaccharide, and on species-specific DNA and RNA sequences from the site of infection or from remote sites such as urine.[252] Definitive diagnosis is confounded in many instances by the need for invasive procedures to obtain specimens (e.g., from the middle ear space) and by nasopharyngeal carriage of pneumococci when sputum is cultured. Pneumococci almost invariably are isolated from CSF in pneumococcal meningitis, even in patients receiving oral antibiotics.[459]

However, establishing the diagnosis of pneumococcal pneumonia is more challenging because sputum rarely is available from children and direct lung puncture is performed very infrequently. Detection of pneumococcal bacteremia to confirm the diagnosis of pneumococcal pneumonia or other localized infection is valuable, but it does not occur frequently and the actual prevalence of bacteremic pneumococcal pneumonia in children is not known,[529] although a study suggests that the prevalence is approximately 17 percent (11/64).[359] Therefore, pediatricians must use other methods to diagnose pneumococcal pneumonia. Signs and symptoms significantly associated with bacteremic pneumococcal pneumonia in children include high temperature (>38.9°C [>102°F]), leukocytosis (>15,000/mm^3), and lobar or segmental consolidation.[529] However, the frequency with which these findings are associated with nonbacteremic pneumococcal pneumonia is not known.

With the widespread deployment of pneumococcal vaccine, occult bacteremia caused by *S. pneumoniae* occurs less commonly. The likelihood that a positive blood culture will be a false-positive result is increased if the WBC count is less than 15,000/mm^3, the time for the blood culture to become positive exceeds 24 hours, or the Gram stain result is suggestive of a contaminant.[472] Overall, the frequency with which positive blood cultures are obtained from children with occult bacteremia has declined in comparison to the pre-pneumococcal vaccine era and has declined precipitously since the era before the deployment of the *H. influenzae* type b (Hib) vaccine.

Direct examination of Gram-stained smears of clinically appropriate material remains the fastest diagnostic method and can be augmented if necessary by direct demonstration of capsular swelling of organisms in the presence of anticapsular antisera. The availability of antigen-detection systems that can be used in urine, serum, CSF, and other specimens, such as capsular antigen detection by counterimmunoelectrophoresis and latex agglutination with polyvalent pneumococcal reagent, generally has not improved patient management because of the low sensitivity and specificity of these methods and the fact that they usually are positive only when a Gram stain also is positive. The concentration of pneumococcal capsular antigen in saliva was evaluated by latex agglutination in a study consisting of children with community-acquired pneumonia and healthy control subjects. None of the children with pneumonia in this study had a positive blood culture, and pneumococcal capsular antigen was detected in the saliva of 27 percent of children with pneumonia versus 17 percent of control subjects. More affected children (20%) than healthy control subjects (2%) had a pneumococcal capsular antigen titer of 10 or greater (p <0.01). Quantitative measurement of pneumococcal capsular antigen in saliva may be valuable in helping make an etiologic diagnosis in children with pneumonia, but its sensitivity is poor and it is confounded by false-positive results caused by pneumococcal carriage.[164]

A rapid (15-minute) immunochromatographic membrane test to detect pneumococcal polysaccharide capsular antigen in urine samples (Binax NOW) has been developed and was evaluated in the diagnosis of bacteremic and nonbacteremic pneumococcal pneumonia. Urine samples were studied in 51 patients with bacteremic and nonbacteremic pneumonia caused by *S. pneumoniae;* the pneumonia was diagnosed by blood culture, and pneumococcal polysaccharide capsular antigen was detected by counterimmunoelectrophoresis in urine samples. Pneumococcal antigen was detected in urine by the immunochromatographic membrane test in 41 of 51 patients with pneumococcal pneumonia (80.4%), including 23 of 28 bacteremic cases (82.1%) and 18 of 23 nonbacteremic cases (78.3%). Antigen also was detected in 7 of 16 patients with a diagnosis of presumptive pneumococcal pneumonia (43.7%) and in 1 of the 16 patients with pneumonia but in whom no pathogen was identified. The specificity of the immunochromatographic membrane test was 97.2 percent, but its sensitivity was only approximately 80 percent, thus limiting its value.[164] Furthermore, the usefulness of this test is questionable because the antigen was detected in the urine in 30 of 138 (22%) healthy children with nasopharyngeal carriage of *S. pneumoniae* versus only 3 of 71 (4%) noncarriers (p < .001).[211] Thus, the test was shown to be often positive in healthy pneumococcal carriers.

One recent study found that immunochromatographic testing for *S. pneumoniae* in CSF was both 100 percent sensitive and specific. The simplicity of the test and the longevity of the CSF antigen even after treatment suggest potential utility of this method in identifying *S. pneumoniae* meningitis in resource-poor countries with widespread prehospital antimicrobial use.[466] Another study showed immunochromatographic testing to be more sensitive than culture in detecting *S. pneumoniae* as the causative agent in thoracic empyema.[425]

Newer molecular-based methods for establishing the diagnosis of pneumococcal disease include the use of DNA probes to detect pneumolysin, autolysin, and PsaA protein, but considerable practical problems must be overcome before these methods will be applicable clinically.[117] Examples include a commercial method involving real-time PCR for simultaneous detection of *Neisseria meningitidis*, *Haemophilus influenzae*, and *S. pneumoniae* in patients suspected of having meningitis and septicemia. This method is based on detection of the pneumolysin gene for *S. pneumoniae* and uses a single-tube, 5′-nuclease multiplex PCR assay on samples of CSF, plasma, serum, and whole blood. Amplified products

are monitored with sequence-specific, fluorescent dye-labeled probes. The sensitivity of using clinical samples (CSF, serum, plasma, and whole blood) from culture-confirmed cases of *S. pneumoniae* infection was 91.8 percent. The multiplex assay also was used to test a large number of culture-negative samples, which resulted in the detection of numerous cases of meningococcal, *H. influenzae*, and pneumococcal disease that had not been detected by culture.[518] However, whether these results are true positives or false positives is not known; and in another study, although the sensitivity of PCR amplification of the pneumolysin gene in the serum and CSF of infants and children with culture-proven pneumococcal bacteremia and meningitis was 100 percent, the specificity was poor, with 17 percent of healthy control subjects having positive results.[117] The prevalence of false-positive reactions was highest (33%) in 2-year-old children, the age group with the highest rate of nasopharyngeal carriage of pneumococci. Therefore, although PCR analysis of serum and CSF is a sensitive test for the detection of *S. pneumoniae* in these sites, its high rate of positivity in healthy control subjects as a result of nasopharyngeal carriage limits its utility in detecting systemic pneumococcal infection.[117]

Another rapid PCR method involving the use of a set of primers that amplify 273 base pairs of the autolysin gene has been developed to identify *S. pneumoniae*. In addition, three sets of primers were designed to amplify a 240-base pair fragment of the PBP2B gene *(pbp2b)* of penicillin-susceptible *S. pneumoniae* and two common *pbp2b* mutations present in penicillin-resistant *S. pneumoniae* so as to simultaneously identify the penicillin susceptibility of strains. The autolysin gene was identified in all 1062 clinical isolates of *S. pneumoniae* evaluated. In addition, 98.9 percent of 621 penicillin-susceptible isolates were shown to have DNA fragments amplified by the penicillin-susceptible primers, whereas 72.1 percent of 441 penicillin-resistant isolates were detected by the penicillin-resistant *S. pneumoniae* primers.[540] A gene probe for the gene encoding the PsaA protein also has been developed on the basis of PCR assay. PsaA was confirmed to be present in representative strains of all 90 known (at that time) serotypes of *S. pneumoniae*. The specificity of the assay was verified by the lack of signal from analysis of heterologous bacterial species (n = 30) and genera (n = 14), including viridans group streptococci. The potential of the assay for clinical application was shown by its ability to detect pneumococci in culture-positive nasopharyngeal specimens.[371]

Whereas a wide variety of molecular methods have been developed for the diagnosis of pneumococcal disease, use of these methods to rapidly detect *S. pneumoniae* remains problematic, with assays such as those targeting the pneumolysin gene cross reacting with other streptococcal species while assays that target the autolysin and *psaA* genes appear to be more specific.* The significance and clinical implications of *S. pneumoniae* DNA detected in clinical samples is therefore difficult to determine at this time.[58]

Susceptibility Testing

Susceptibility testing of pneumococci has been well standardized, and testing can be performed by determination of the minimal inhibitory concentration (MIC) and, for selected agents, by disk diffusion.[98] MICs can be performed by macrodilution or microdilution in cation-supplemented Mueller-Hinton broth enhanced with 5 percent whole defibrinated sheep or horse blood or 5 percent lysed and centrifuged horse blood.[98] If sulfonamides are tested, only the latter supplement should be used to avoid the presence of sulfonamide antagonists. MICs also can be determined by dilution in Mueller-Hinton agar supplemented as just described. Many systems based on frozen or dried microdilution trays are available commercially and used extensively for surveillance testing.[250] As with any system, commercial microdilution panels should be validated and used with appropriate quality controls. Another method for determination of MICs, the E-test, is much simpler to use than are the other methods for MIC determination. The E-test consists of a calibrated antibiotic-impregnated plastic strip that is applied to the surface of an inoculated agar plate. An antibiotic gradient is produced that results in an elliptical zone of inhibition after incubation. The MIC is read at the point where the ellipse of inhibition meets the strip. Evaluation of the E-test has shown that this method generally is reliable, although problems are encountered with some agents because acidification of the medium occurs during incubation of the plates in CO_2, which is required to ensure the growth of clinical isolates. Agents particularly affected are macrolides and some quinolones.

Disk diffusion also has been standardized well for testing pneumococci against selected agents. Distinction between susceptible and resistant strains is accomplished readily by using the current Clinical and Laboratory Standards Institute (CLSI) method involving macrolides, tetracycline, chloramphenicol, trimethoprim-sulfamethoxazole, and clindamycin.[98,252] For testing penicillin and other β-lactams, disk diffusion is used best as a screening method with 1-μg oxacillin disks that have a susceptible cutoff zone of 20 mm or larger. Strains with zones of 20 mm or larger are fully susceptible to penicillin and other β-lactams. However, strains with zones that are less than 20 mm need to have MICs of penicillin and other appropriate β-lactams determined. Penicillin-susceptible strains with MICs of 0.06 μg/mL usually screen out with resistant strains.

Although interpretative categories for clarifying the significance of MIC values are available, many limitations to the currently available CLSI pneumococcal breakpoints exist, particularly for agents that can be administered in multiple-dosing regimens and by multiple routes of administration and that are used for infections in different body sites. Breakpoints for parenteral β-lactam agents generally are based on the use of agents in meningitis, whereas those of oral β-lactam agents are based on nonmeningeal infections such as otitis media.[98,252] Nonmeningeal breakpoints for some parenteral β-lactam agents were introduced in 2002, which to some extent will avoid the use of non-β-lactam agents for serious

nonmeningeal pneumococcal infections. These breakpoint changes classify strains previously interpreted as intermediate in sensitivity to penicillin G, cefotaxime, and ceftriaxone as susceptible if the agents are administered parenterally to treat pneumonia and other nonmeningeal infections. Pharmacokinetic and pharmacodynamic parameters recently have been shown to correlate with clinical outcome and offer a more rational approach to predicting antimicrobial efficacy and determining clinically relevant susceptibility breakpoints.[104,113,254,257]

The activity of antimicrobial agents against penicillin-susceptible, penicillin-intermediate, and penicillin-resistant pneumococci, based on the original penicillin breakpoints (susceptible, ≤0.06 μg/mL; intermediate, 0.12 to 1 μg/mL; resistant, ≥2 μg/mL), is shown in Table 85-3.[253] There is considerable variation in antimicrobial susceptibility between pneumococcal serotypes, and the in vitro activity of selected antimicrobial agents against a collection of 891 pneumococci collected in 2008 from 22 centers in the United States is shown in Table 85-4 for all isolates and for the 11 predominating serotypes.[255] All serotype 7F isolates were susceptible to all agents tested, as were more than 95% of serotype 3 isolates. In contrast, many isolates of serotypes 19A, 6C, and 19F were multidrug resistant.

Antibiotic Resistance

Resistance to β-Lactam Drugs

Widespread resistance to β-lactam and other drug classes has evolved in the most common pathogens, including *S. pneumoniae*. Although pneumococci are naturally transformable organisms, β-lactamase production never has been described in this organism. Instead, a much more complex resistance mechanism has evolved in *S. pneumoniae* that is mediated by sophisticated restructuring of the targets of the β-lactams, the PBPs, and by other newly described mechanisms.[208] The PBP targets in penicillin-resistant strains of *S. pneumoniae* are modified, low-binding affinity versions of the native PBPs. PBP targets may be modified by mutation or by transformation and homologous recombination with DNA from the PBP genes of viridans streptococci. The level of resistance is determined by how many and to what extent targets are modified.[89] Restructuring of PBPs is mediated by stepwise alterations in PBPs. The high-molecular-weight PBPs—types 1A, 2X, and 2B—that usually are detected in *S. pneumoniae* are involved in transpeptidase activity and play an important role in resistance.[208] Alterations in PBP-2B are associated with low-level resistance to penicillin, and alterations in PBP-2X mediate low-level resistance to cephalosporins. The additional alterations in PBP-1A raise penicillin MICs to 1 μg/mL or greater and cefotaxime MICs to 0.5 μg/mL or greater. Genomic comparison between *S. pneumoniae* and commensal *S. mitis* and *S. oralis* strains has documented the mosaic nature of PBPs among these species, with pneumococci acquiring their altered PBP genes from *S. mitis* and *S. oralis*.[207] Many other mosaic gene clusters not associated with penicillin resistance also have been found.[175] The capacity to produce branched cell wall stem peptides encoded by altered *murM* and *murN* genes, as well as altered PBPs, is required for expression of penicillin resistance in *S. pneumoniae*.[158] The *fibA* and *fibB* genes, which are homologous to the *Staphylococcus aureus femA/B* genes required for expression of methicillin resistance in this organism, encode proteins involved in the formation of interpeptide bridges and also are required for expression of PBP-mediated penicillin resistance.[569] Other mechanisms of β-lactam resistance have been described in laboratory mutants and in a clone of Hungarian pneumococcal strains with notably high levels of β-lactam resistance (penicillin MIC, 16 μg/mL; cefotaxime MIC, 4 μg/mL).[208,500]

Resistance to Non-β-Lactam Drugs

The molecular and genetic mechanisms of resistance to macrolides, chloramphenicol, tetracycline, fluoroquinolones, and trimethoprim-sulfamethoxazole in *S. pneumoniae* also have been determined. Resistance genes for several agents are carried on a transposon, Tn1545.[103] It confers resistance to three antimicrobial classes—kanamycin *(aphA-3)*, macrolide-lincosamide-streptogramin B-type antibiotics *(ermB)*, and tetracycline *(tetM)*. This transposon has been conjugated and transposed to the chromosome of *Enterococcus faecalis*, oral streptococci, and *Listeria monocytogenes*. The properties of this transposon account for the sudden emergence, rapid dissemination, and stabilization of resistance to multiple antibiotics in *S. pneumoniae* in the absence of plasmids.

Resistance mechanisms include the production of chloramphenicol acetyltransferase, an enzyme capable of catalyzing the conversion of chloramphenicol to nonfunctional derivatives. Chloramphenicol acetyltransferase is encoded by a chloramphenicol acetyltransferase *(cat)* gene identical to the *cat* gene from the *S. aureus* plasmid pC194. Tetracycline resistance occurs through ribosomal protection encoded by the genes *tetM* and *tetO*. The tetM and tetO proteins are thought to cause tetracycline to be released from the ribosome. Resistance to fluoroquinolones primarily involves mutations in the DNA gyrase gene *gyrA* and in the topoisomerase IV genes *parC* and *parE*, as well as an efflux mechanism that affects some fluoroquinolones. Resistance to trimethoprim is mediated through a single amino acid substitution in the chromosomal dihydrofolate reductase gene of *S. pneumoniae*, which is thought to disrupt the bond with trimethoprim without affecting the action of dihydrofolate reductase. Sulfonamide resistance appears to result from repetitions of one or two amino acids in the chromosomal dihydropteroate synthase.[579]

Two major mechanisms have been described for resistance to erythromycin. Coresistance to macrolides, clindamycin, and streptogramin B-type antibiotics is a result of modification of the ribosome through methylation of an adenine residue in domain V of the 23S rRNA. Methylation is encoded by a methylase gene, *ermB* (previously called *ermAM*). Resistance to 14- and 15-membered macrolides (erythromycin, azithromycin, and clarithromycin) but not to 16-membered macrolides (roxithromycin, josamycin, and spiramycin), ketolides, or clindamycin is a result of efflux of the antibiotic from the cell; such

TABLE 85-3 **Activity of Antimicrobial Agents Against Penicillin-Susceptible, Penicillin-Intermediate, and Penicillin-Resistant Pneumococci***

Agent Class	Antimicrobial Agent	Breakpoints (≤S/I/≥R) μg/mL	MIC_{90} (μg/mL)

resistance is encoded by the gene *mefE* in *S. pneumoniae* and appears to be emerging rapidly as the predominant mechanism of resistance to erythromycin in many countries.[175] Other macrolide resistance mechanisms that have been described include mutations in position 2059 of the 23S rRNA and in genes encoding ribosomal protein L4.[519]

Vancomycin Tolerance

Although vancomycin resistance has not been described in pneumococci, antibiotic tolerance, or the ability of bacteria to survive but not grow in the presence of antibiotics, has been described. It has been shown to be caused by loss of function of the VncS histidine kinase

TABLE 85-4 **In Vitro Activity of Selected Antimicrobial Agents Against 891 Pneumococci Collected in 2008 from 22 Centers in the United States for All Isolates and for the 11 Predominating Serotypes**

Agent (CLSI Breakpoint for Susceptibility [μg/mL])	Percent Susceptibility of Isolates by Serotype (No. of Isolates)

TMP-SMX, trimethoprim-sulfamethoxazole.
Modified from Jacobs MR, Good CE, Windau AR, et al. Activity of ceftaroline against recent emerging serotypes of *Streptococcus pneumoniae* in the United States. *Antimicrob Agents Chemother* 2010;**54**:2716–19.

of a two-component gene expression sensor-regulator system in *S. pneumoniae* that produces tolerance to vancomycin and other classes of antibiotics.[390]

Evolution of Antibiotic Resistance

Pneumococci initially were susceptible to many antimicrobial agents, but they became resistant with varying degrees of rapidity to many of these agents. The earliest example was the development of resistance to optochin (ethylhydrocupreine) when this agent was used experimentally in mice in the early part of the 20th century. With the introduction of sulfonamides in 1939, pneumococci similarly exhibited an ability to acquire resistance in experimental infections in mice, as well as in a human case of meningitis.[292] Sulfonamide resistance was identified sporadically thereafter, and a trimethoprim-sulfamethoxazole-resistant strain was recognized first in 1972. Trimethoprim-sulfamethoxazole resistance subsequently has become widespread in virtually all serotypes throughout the world, including developing countries, and resistance to this agent is greater than that to any other antimicrobial class worldwide.[231] Tetracycline resistance emerged in the 1960s and chloramphenicol resistance in 1970. However, little attention was paid to the development of resistance in this species until 1977, when isolates resistant to several antimicrobial classes, including penicillins, chloramphenicol, tetracyclines, macrolides, clindamycin, and trimethoprim-sulfamethoxazole, were detected in South Africa.[23,256]

Subsequently, multiresistant clones of pneumococci have spread throughout many regions of the world. Noteworthy is that multiresistant clones are confined mostly to serotype 14 and serogroups 6, 9, 19, and 23.[123] Whereas resistance to penicillins occurs in a stepwise fashion and in many cases can be overcome by using β-lactams with appropriate pharmacokinetics, resistance to other drug classes usually is absolute and distinct populations of strains are found to be susceptible and resistant to agents such as macrolides, clindamycin, tetracyclines, trimethoprim-sulfamethoxazole, and chloramphenicol. Unlike enterococci, resistance to vancomycin has not developed in pneumococci yet, although vancomycin-tolerant strains have been detected.[45,228]

Cross-resistance among *S. pneumoniae* to macrolides and other classes of antibiotics usually increases with increasing MICs to penicillin (Fig. 85-13).[254] Whereas only 6 percent of penicillin-susceptible pneumococci are resistant to macrolides and 14 percent to trimethoprim-sulfamethoxazole, approximately half of the penicillin-intermediate isolates were resistant to these agents. In the case of penicillin-resistant strains, three fourths were resistant to macrolides, 90 percent to trimethoprim-sulfamethoxazole, and 28 percent to clindamycin. However, this pattern is not the case in all countries and at least one multiresistant clone resistant to chloramphenicol, tetracycline, erythromycin, clindamycin, and trimethoprim-sulfamethoxazole has remained susceptible to penicillin.[126,518]

Strains of *S. pneumoniae* were exquisitely susceptible to penicillin (MICs of 0.01 to 0.03 μg/mL) when this agent initially was used clinically in the 1940s and 1950s, and this MIC range is referred to as the baseline activity of penicillin against "wild-type" *S. pneumoniae*.[252] Evolution

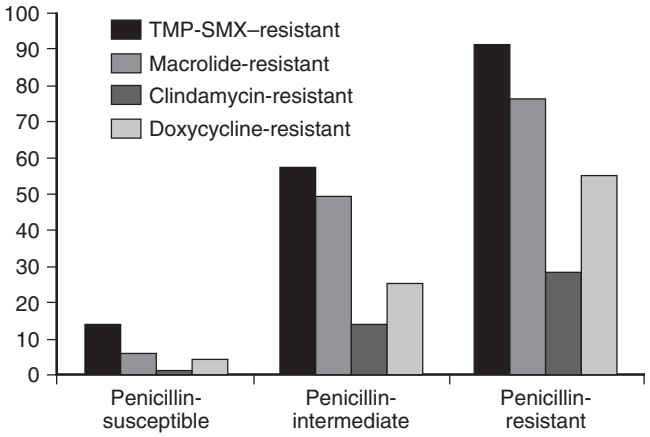

FIGURE 85-13 ■ Pneumococci often are resistant to several drug classes, and cross-resistance to macrolides and other classes of antibiotics increases as minimal inhibitory concentrations of penicillin increase. TMP-SMX, trimethoprim-sulfamethoxazole. (From Jacobs MR. Antimicrobial-resistant *Streptococcus pneumoniae:* trends and management. *Expert Rev Anti Infect Ther* 2008;**6**:619–35.)

of resistance to this class of agents was noted first when a few strains of *S. pneumoniae* were isolated in the 1960s in Australia and New Guinea. These strains had decreased susceptibility to penicillin, with MICs of 0.1 to 0.25 μg/mL, approximately 10-fold higher than the MICs of baseline strains. Strains with penicillin MICs of 2 to 4 μg/mL, approximately 100-fold higher than baseline strains, were isolated in South Africa in 1977, and, subsequently, strains with even higher MICs (16 μg/mL, approximately 1000-fold higher than baseline strains) were described in Hungary.[500] Pneumococci conventionally are classified as penicillin-susceptible if the MICs are 0.06 μg/mL or less, intermediate if the MICs are 0.12 to 1.0 μg/mL, and resistant if the MICs are 2.0 μg/mL or greater. This classification is useful mainly in characterizing strains as fully susceptible to β-lactams if susceptible or as having decreased susceptibility if intermediate or resistant. Strains with such decreased susceptibility are better referred to as β-lactam drug challenged because the mechanism of resistance can be overcome if the pharmacokinetics of the β-lactam drug used in serum or at the site of infection exceeds the MIC for 40 to 50 percent of the dosing interval.[105] Similar variations in MIC ranges are seen with all β-lactams, although MIC ranges for many β-lactams are much higher than that for penicillin itself. Agents such as ampicillin, amoxicillin, cefotaxime, and ceftriaxone have MIC ranges similar to that of penicillin, whereas agents such as cefazolin, cefaclor, cefprozil, ceftazidime, and cefixime have much higher MIC ranges. For example, the baseline activity of cefaclor against *S. pneumoniae* is 0.5 to 1 μg/mL, which is a concentration 20- to 30-fold higher than that required for penicillin to inhibit the most susceptible strains. Changes in susceptibility that occur over the course of time were illustrated in a study of recent versus archived otitis media strains. In this study, the MIC_{90} for cefaclor against archived isolates was 1 μg/mL, whereas the MIC_{90} against recent isolates was greater than 64 μg/mL.[251] A few agents, such as imipenem and meropenem, have slightly lower MIC ranges than those of penicillin. The proportion of pneumococci that are penicillin susceptible, intermediate, and resistant vary considerably throughout the world.

Resistance to macrolides in strains of *S. pneumoniae* was noted first in 1964 and was detected sporadically in the United States until it became widespread in the latter half of the 1990s.[231,243,292] The baseline activity of macrolides (0.03 μg/mL) and MIC distributions (1000-fold concentration range, 0.03 to >32 μg/mL) against *S. pneumoniae* are somewhat similar to those of penicillin. The MIC distribution of macrolides is trimodal, with strains being exquisitely susceptible (erythromycin MIC, <0.03 μg/mL) or highly resistant (erythromycin MIC, >32 μg/mL) or demonstrating low level resistance (MICs of 1 to 16 μg/mL).[152] These distributions closely correlate with macrolide ribosomal methylase and efflux resistance mechanisms. The prevalence of macrolide resistance and reports of clinical failure resulting from strains with efflux and ribosomal methylase resistance mechanisms continue to increase. Some authors, however, have argued that isolates with efflux-mediated resistance could be susceptible to the high intracellular concentrations that these agents achieve in phagocytic cells and in epithelial lining fluid of the alveoli.[15] However, no clinical or animal data support these arguments for extracellular pathogens such as *S. pneumoniae*, whereas considerable clinical and animal data support the use of current breakpoints.[42,104,105,365] The rising incidence of macrolide-resistant pneumococci was directly proportional to the increasing use of macrolides in various communities and age groups.[173,243,423]

Strains with multiple antibiotic resistance have greater selective advantages than do strains resistant to just one antibiotic because the opportunity for positive selection is increased as the number of drug classes to which isolates are resistant increases.[291] Exposure to different classes of antibiotics allows more opportunity for selective advantage to a multiple antibiotic-resistant organism than to a monoresistant strain, which must wait to encounter the one antibiotic to which it is resistant and is likely to be killed by agents of other antibiotic classes. Thus, the increasing prevalence of antibiotic-resistant pneumococci is associated with the increasing prevalence of multidrug-resistant strains. Therefore, one is not surprised that the use of one class of antibiotics (mainly macrolides and trimethoprim-sulfamethoxazole) can be associated with an increase in resistance to other classes of antibiotics (mainly β-lactam drugs).[3,24,190,423] Many authorities now think that antibiotic agents such as the newer macrolides (e.g., clarithromycin and azithromycin) and trimethoprim-sulfamethoxazole are stronger promoters of antibiotic resistance among *S. pneumoniae* strains than are the β-lactam drugs.[24,190,423] Researchers also have suggested that among the β-lactam drugs, cephalosporins are stronger promoters of resistance in *S. pneumoniae* than are the aminopenicillins.[173,469] Although many strains are resistant to tetracyclines and macrolides, they are susceptible to the new tetracycline derivatives, the glycylcyclines, as well as to streptogramins, ketolides, glycopeptides, and rifampin. Many strains are resistant to

trimethoprim-sulfamethoxazole worldwide, with more than 40 percent being resistant in the United States. Fluoroquinolones with antipneumococcal activity (e.g., gatifloxacin, levofloxacin, moxifloxacin) are active against most strains of *S. pneumoniae;* however, in several countries where fluoroquinolones have been prescribed widely, clinically relevant levels of resistance have been described.[90,231] No doubt, antibiotic resistance will continue to evolve and challenge us.

HOST DEFENSES

Although anticapsular antibody is the most prominent protective mechanism against pneumococcal infection, many host responses to infection occur and many other factors are associated with protection against disease.[379] Pneumococcal infection and disease have been modeled in several animal species. Most are models of sepsis arising from intravenous or intraperitoneal inoculation of bacteria, and only a few were designed to study disease arising from intranasal infection. Chinchillas provide the only animal model of middle ear pneumococcal infection in which the disease can be produced by very small inocula injected into the middle ear or intranasally. This model, developed at the University of Minnesota in 1975, has been used to study pneumococcal pathogenesis at a mucosal site, the immunogenicity and efficacy of pneumococcal capsular polysaccharide vaccine antigens, and the kinetics and efficacy of antimicrobial drugs.[181]

Anticapsular Serum IgG Antibody

IgG to the capsular polysaccharide of *S. pneumoniae* is thought to provide the greatest degree of protection against systemic pneumococcal disease, as well as limited protection against colonization. The reference method for measurement of antibody is the opsonophagocytosis assay, which involves serial dilutions of serum, viable pneumococci, complement, and viable PMNs incubated together for 1 hour.[455] An infant mouse assay system for assessment of protective concentrations of human serum pneumococcal anticapsular antibodies correlated well with opsonophagocytic titer but not with naturally occurring IgG antibody concentrations or IgG produced in response to nonconjugated polysaccharide vaccines, as determined by ELISA.[267,384] However, the ELISA method of serotype-specific antibody assay with absorption of cross-reacting antibody to cell wall polysaccharides does correlate well with protection after vaccination with conjugated vaccine, and it is the method used most commonly to predict serotype-specific immunity.[22,546,547]

The development of a phagocytosis assay based on flow cytometry has not overcome the limitations of the ELISA method and is inferior to the opsonophagocytosis method.[260] Investigation of polymorphisms in the variable region of IgG that affect protective function has indicated that the capsular polysaccharide antibody repertoire in adults is derived from memory B-cell populations that have switched class and undergone extensive hypermutation.[336] Functionally disparate anticapsular polysaccharide antibodies can arise within individuals both by activation of independent clones and by intraclonal somatic mutation, which illustrates the complexity of assaying and interpreting serum capsular polysaccharide antibody levels.

Anticapsular IgA Antibody

The role of IgA in the control of invasive mucosal pathogens such as *S. pneumoniae* is understood poorly. Human pneumococcal capsular polysaccharide-specific IgA initiates dose-dependent killing of *S. pneumoniae* in the presence of complement and phagocytes. The majority of specific IgA in serum is of the polymeric form, and the efficiency of killing initiated by this polymeric form exceeds that of monomeric IgA-initiated killing. In the absence of complement, specific IgA induces minimal bacterial adherence, uptake, and killing. Killing of *S. pneumoniae* by resting phagocytes with immune IgA requires complement, predominantly via the C2-independent alternative pathway, which in turn requires factor B but not calcium. Pneumococcal capsule-specific IgA may have distinct roles in effecting the clearance of pneumococci in the presence or absence of inflammation, and the polymeric form may control pneumococcal infections locally and after the pathogen's entry into the bloodstream by several mechanisms.[258]

Phagocytosis and Leukocyte IgG Receptors

IgG-mediated phagocytosis by PMNs is the main defense against *S. pneumoniae*. Two leukocyte IgG receptors, FcγRIIa and FcγRIIIb, are expressed constitutively on PMNs. Blocking experiments have shown that FcγRIIa is crucial for opsonophagocytosis of serum-opsonized *S. pneumoniae*. In adults, serum-induced phagocytic activity depends mainly on antipneumococcal IgG2 antibodies.[454] However, in infants and young children, the main response to pneumococcal conjugate vaccines occurs in the IgG1 subclass.[22,554] Investigators have suggested that IgG1 subclass antibodies are at least as highly functional as is IgG2.[146] Recruitment and function of neutrophils also are important host defenses. In a pneumococcal infection model in immunocompetent and immunodeficient mice intranasally infected with *S. pneumoniae* type 2, immunocompetent BALB/c mice were resistant and immunodeficient CBA/Ca mice were susceptible to infection. BALB/c mice recruited significantly more neutrophils in the lungs, and inflammatory lesions were visible much earlier than in CBA/Ca mice.[185]

Antibodies to Surface Proteins and Pneumolysin

PspA, PsaA, and pneumolysin are common to virtually all pneumococcal isolates. The development of antibodies to PspA, PsaA, and pneumolysin as a result of pneumococcal infection and carriage in young children was determined by measurement of serum antibodies to these proteins by ELISA in children at ages 6, 12, 18, and 24 months and in their mothers. All age groups were shown to produce antibodies to the three proteins, which increased with age and were associated strongly with

pneumococcal exposure as a result of carriage or AOM.[439] IgA to PspA, PsaA, and pneumolysin has been detected by ELISA in the saliva of children aged 6 to 24 months.[493] This finding was associated with pneumococcal carriage and otitis media.

Serum antipneumolysin IgG at the time of hospital admission has been found to be higher in patients with nonbacteremic pneumococcal pneumonia than in those with bacteremic pneumococcal pneumonia or uninfected control subjects.[383] Serum antipneumolysin IgG levels also rose significantly during convalescence in patients with bacteremic pneumonia, and the levels attained were equal to those observed in nonbacteremic patients. Children aged 6 to 24 months were shown to produce antibodies to pneumolysin, and antibody concentrations increased with age and were associated strongly with pneumococcal exposure, whether by carriage or infection such as AOM.[439] Infants also have been shown to mount a specific antibody response to pneumolysin during AOM.[440]

Defense Mechanisms of the Spleen

The spleen is the principal organ that clears pneumococci from the bloodstream.[307,379] Opsonized particles are removed from the circulation by the liver; but with decreasing opsonization, the spleen increasingly assumes the role of clearance. The slow passage of blood through the spleen and the prolonged contact time with reticuloendothelial cells in the cords of Billroth and the splenic sinuses allow time for the removal of nonopsonized particles. Overwhelming pneumococcal infection occurs in children and adults whose spleens have been removed or do not function normally. Pneumococcal disease progresses so rapidly in such individuals that pneumonia is not detectable clinically or by chest radiographs, although it is seen at autopsy. The increase in the incidence of pneumococcal bacteremia and meningitis in children with sickle-cell disease is due largely to splenic dysfunction. Splenectomy also results in a marked, sustained elevation in risk for severe *S. pneumoniae* infection in HIV-infected patients.[428]

Vitamin A

The association of nasopharyngeal colonization with *S. pneumoniae* and vitamin A supplementation in infants in an area with endemic vitamin A deficiency in southern India showed that neonatal vitamin A supplementation delayed the age at which colonization occurs; therefore, it may play a role in lowering morbidity rates associated with pneumococcal disease.[101]

C-Reactive Protein

C-reactive protein (CRP) is a normal constituent of human serum that is synthesized by hepatocytes and induced by proinflammatory cytokines. The function of this acute-phase reactant includes activation of complement and enhancement of opsonophagocytosis. CRP binds to phosphorylcholine, a constituent of eukaryotic membranes that also is found on the cell surface of the major bacterial pathogens of the human respiratory tract, including *S. pneumoniae* and *H. influenzae*. CRP is present in inflamed (0.17 to 42 μg/mL) and uninflamed (<0.05 to 0.88 μg/mL) secretions from the human respiratory tract in sufficient quantities to have an antimicrobial effect. In addition, the *CRP* gene was expressed in human respiratory epithelial cell cultures. The complement-dependent bactericidal activity of normal nasal airway surface fluid and sputum was abolished when the secretions were pretreated to remove CRP. Human respiratory epithelial cells are capable of expressing CRP, and this protein may contribute to bacterial clearance in the human respiratory tract.[194]

Platelet-Activating Factor Receptors of Airway Epithelial Cells

Adherence of pneumococci to cultured human tracheal epithelial cells increased after exposure to acid and decreased after exposure to a specific inhibitor of the receptor for platelet-activating factor.[247] Exposure to acid thus may stimulate the adherence of *S. pneumoniae* to airway epithelial cells via increases in platelet-activating factor receptors. The clinical significance of these findings is not clear.

Cytokines

Polymorphonuclear granulocytes, which provide a major defense against *S. pneumoniae* infection, are attracted to and activated by various cytokines, including IL-1β, IL-6, TNF-α, IL-8, IL-10, IL-12, interferon-γ, and granulocyte-macrophage colony-stimulating factor.[28] The inflammatory response in bacterial meningitis also is mediated by TNF-α and IL-1, which are produced in the subarachnoid space by cells such as leukocytes, astrocytes, and microglia.[406] Inoculation of pneumococcal cell wall components directly into the CSF of rabbits also results in the induction of an inflammatory response with pleocytosis and increased levels of CSF TNF-α and IL-1.[195] Both TNF-α and IL-1β have been shown to increase mucosal adhesion of pneumococci to tracheal epithelium in a chinchilla trachea whole-organ perfusion model.[536]

L-Ascorbic Acid (Vitamin C)

Degradation of the connective tissue component hyaluronic acid by the hyaluronate lyase produced by *S. pneumoniae* is inhibited competitively by L-ascorbic acid (vitamin C).[324] One L-ascorbic acid molecule was found to bind to the active site of the enzyme. The high concentration of L-ascorbic acid in human tissues probably provides a low level of natural resistance to pneumococcal invasion by this mechanism.

Leukotrienes

Leukotrienes are produced by macrophages and are considered important for antibacterial defense in the lung. Leukotrienes comprise a group of highly potent lipid

mediators synthesized by the enzyme 5-lipoxygenase. Multidrug-resistance protein 1 (mrp1) is a transmembrane protein responsible for the cellular extrusion of leukotrienes from macrophages. In a mouse pneumonia model, mrp1-deficient mice display diminished growth of pneumococci in the lungs and low mortality by a mechanism that involves increased release of leukotriene B_4.[477] Pneumococci also induce the production of leukotrienes in the middle ear, which has been related to upregulation of two genes that govern the lipoxygenase pathway.[328]

Human Alveolar Macrophage Binding and Phagolysosomes

Human alveolar macrophages are the major resident phagocytic cells of the lung. After contact with macrophages, bacteria enter phagosomes, which gradually acquire the characteristics of terminal phagolysosomes, with incorporation of lysosome-associated membrane protein. Opsonization with serum containing immunoglobulin resulted in significantly greater binding of pneumococci to macrophages than did opsonization with immunoglobulin-depleted serum.[191] Binding, intracellular localization, and killing of pneumococci by macrophages all are increased significantly by opsonization with serum containing immunoglobulin, complement, or both.

Intracellular Killing

Once pneumococci undergo phagocytosis by "professional" phagocytes (leukocytes and macrophages), they are killed.[379] However, researchers have shown that pneumococci can enter and survive inside A549 cells, a human lung alveolar carcinoma (type II pneumocyte) cell line.[522] Not all clinical *S. pneumoniae* isolates were capable of penetrating these cells, and the presence of a polysaccharide capsule also reduced their capacity to penetrate A549 cells significantly. The intracellular activity of various antibiotics against pneumococci in A549 cells showed that in the presence of antibiotics for 18 hours, more than 98 percent of the A549 cells were viable and less than 3 percent of the pneumococci that initially were phagocytosed could be detected intracellularly after exposure to peak serum concentrations of penicillin G, azithromycin, moxifloxacin, trovafloxacin, rifampin, and telithromycin.[348]

In the absence of antibiotics, pneumococci were phagocytosed efficiently but then paradoxically went on to kill all the A549 cells within 18 hours. The clinical significance of these findings is unknown.

Complement

The second component of complement (C2) is an important factor associated with host defense against encapsulated organisms. Homozygous deficiency of C2 is the deficiency of complement most commonly inherited. Although C2 deficiency can be asymptomatic, patients usually have either autoimmune disease or recurrent pyogenic infection caused by encapsulated bacteria such as *S. pneumoniae*, *H. influenzae* type b, and *N. meningitidis*. An association between C2 deficiency and IgG subclass deficiency also has been described.[29] *S. pneumoniae* challenge of mice deficient in the third component of complement (C3) results in a 2000-fold increase in organism load in the bloodstream in comparison with control animals.[97] Binding of pneumococcal CbpA to epithelially produced C3 results in adhesion of pneumococci to type II pulmonary epithelial cells. CbpA-deficient pneumococcal mutants and lysates, therefore, fail to bind C3 and demonstrate a moderate decrease in adhesion to type II pulmonary epithelial cells, thus confirming the interaction of CbpA and C3 in adhesion.[501]

Polymeric Immunoglobulin Receptor

pIgR plays a crucial role in mucosal immunity against microbial infection by transporting polymeric immunoglobulins such as IgA across the mucosal epithelium. Polymeric IgA consists of two IgA molecules joined by a small polypeptide J chain. The J chain shows high affinity for the glycoprotein pIgRs of epithelial cells, which are responsible for externalization of polymeric IgA across cell membranes.[264] However, pIgR also can act as a "Trojan horse" and participate in the pathogenesis of IPD as pIgR binds to a major pneumococcal adhesin, CbpA.[599] Expression of pIgR in human nasopharyngeal cells greatly enhances pneumococcal adherence and invasion; this effect is abolished either by insertional knockout of CbpA in pneumococci or by antibodies against either pIgR or CbpA.

Basic Fibroblast Growth Factor

Basic fibroblast growth factor is a neurotrophic factor in the central nervous system that is expressed at high levels in response to seizure or stroke. It also occurs in pneumococcal meningitis, as shown in experimental bacterial meningitis in mice and in children with bacterial meningitis.[241] Patients with meningitis in whom major sequelae or death occurred had much higher levels of CSF basic fibroblast growth factor than did those who survived. In patients with bacterial meningitis who survived, basic fibroblast growth factor decreased significantly in CSF after 24 to 50 hours of administration of antibiotic therapy. However, its biologic role in the pathophysiology of bacterial meningitis is not known.

Granulocyte Colony-Stimulating Factor

In a limited study of 22 non-neutropenic adult patients with pneumococcal meningitis, granulocyte colony-stimulating factor (G-CSF), in addition to cefotaxime and dexamethasone, was administered subcutaneously for 6 days. All patients survived, and in only 1 patient did a complication develop (bilateral hearing deficit). Improvement of inflammation indices in CSF was rapid.[124] However, controlled clinical trials are needed. In a rabbit meningitis model, G-CSF increased the percentage of granulocytes in blood but not in CSF and increased CSF TNF-α and IL-1β concentrations.[474] However, G-CSF

did not reduce the density of apoptotic neurons in the dentate gyrus of the hippocampus. A second study in a rabbit meningitis model used longer pretreatment with G-CSF and showed more positive results.[405] G-CSF pretreatment attenuated meningeal inflammation and enhanced systemic killing of bacteria. Pretreatment with recombinant human G-CSF in a murine model of pneumococcal pneumonia resulted in improved survival with low, but not high, bacterial inocula. Therefore, the benefits of using G-CSF are limited because pneumococci already have recruited large numbers of neutrophils in the lungs by this time.[120]

Intracellular Signaling Pathways

Pneumococcal cell walls activate multiple intracellular signaling pathways in microglial brain cells, with induction of an outwardly rectifying K^+ channel, suppression of the constitutively expressed inwardly rectifying K^+ current, and release of TNF-α, IL-6, IL-12, and other inflammatory mediators.[431] The presence of serum strongly facilitated these effects. The mechanisms involved in microglial activation by pneumococcal cell walls were different from those activated by gram-negative lipopolysaccharide.

Lactoferrin

Human lactoferrin is an iron-binding glycoprotein that is particularly prominent in exocrine secretions and leukocytes and also is found in serum, especially during inflammation. It is able to sequester iron from microbes and has immunomodulatory functions, including inhibition of both activation of complement and production of cytokines. Binding of human lactoferrin to the surface of *S. pneumoniae* depends entirely on PspA.[206] Prevention of the binding of lactoferrin to pneumococcal PspA could be an important host defense mechanism.

Mannose-Binding Lectin

Mannose-binding lectin (MBL) is a key mediator of innate host immunity that activates the complement pathway and directly opsonizes some infectious pathogens. Mutations in three codons in the MBL gene have been identified, and individuals homozygous for a mutant genotype have very little or no serum MBL. In a study conducted in the United Kingdom of 229 patients in whom *S. pneumoniae* was isolated from sterile sites, 28 (12%) were homozygous for MBL codon variants versus only 18 of 353 (5%) control subjects (odds ratio, 2.59; 95% confidence interval [CI], 1.39 to 4.83).[461]

CLINICAL SYNDROMES

The pneumococcus causes disease over the entire age spectrum from early-onset neonatal sepsis to pneumonia, IPD, and meningitis in geriatric patients. It is found frequently in the nasopharynx of children younger than 5 years of age, yet only a small fraction of colonized children develop either invasive disease syndromes or respiratory tract infection. New data from both animal and human studies suggest that colonization is associated with a mild inflammatory response within the nasopharynx that, in general, resolves spontaneously.[272,588] In those children in whom the pneumococcus evades host defenses, the organism has the potential to cause local respiratory tract illnesses such as AOM, acute sinusitis, and nonbacteremic pneumonia or to enter the bloodstream and result in a spectrum of clinical syndromes, including bacteremia, sepsis, meningitis, or focal infections, such as septic arthritis, osteomyelitis, endocarditis, soft tissue infection, or peritonitis. Infection may also spread directly to the central nervous system from the nasopharynx in children with cochlear implants and in children with basal skull fracture and CSF leak. Peritonitis is also reported, most often in children with nephrotic syndrome. Colonization of the genital tract in women is also reported and may be the source for early-onset sepsis in vulnerable neonates or spread through the fallopian tubes to the peritoneal cavity.

The clinical signs and symptoms of patients with pneumococcal infection can be nonspecific, reflective of the bacteremia/sepsis syndrome, or specific to the organ system involved. In general, bacteremia presents as high fever and temperatures that can exceed 40° C (104° F).[38] Pneumococcal pneumonia most often presents as fever, cough, and tachypnea and possibly chest pain when consolidation is also present.

Bacteremia and "Occult" Bacteremia

Unsuspected or "occult" bacteremia in children 3 to 36 months of age who have fever without evidence of toxicity or focal infection has been reported in up to 4 percent of febrile infants and toddlers in the era before the introduction of pneumococcal conjugate vaccines. When clinical practice includes performance of blood cultures on febrile children with mild or moderate toxicity, bacteremia has been identified from emergency or walk-in clinics as well as office practice settings.[72] In the United States, *Streptococcus pneumoniae* represented approximately 60 percent of pathogens identified in children well enough to be discharged home whereas *H. influenzae* type b was identified in up to 25 percent of cases. This distribution was dramatically altered with the introduction of Hib conjugate vaccines, thus increasing the proportion of bacteremic cases from which *S. pneumoniae* was isolated from blood culture to 80 to 90 percent.[12,288,584] Age younger than 24 months and temperature greater than 39° C (102.2° F) were the demographic and clinical features initially described that characterized the majority of children with "occult" pneumococcal bacteremia in U.S. studies. Disease was less common in children younger than 6 months of age. Clinically, the risk for bacteremia increases with increasing temperature, being greatest with temperature greater than 40° C (104° F). Subtle clinical differences in alertness, color, quality of cry, hydration, and responsiveness have been described in bacteremic children compared with otherwise similar febrile children.[353,354,584] Laboratory studies reveal that elevated white blood cell counts above 15,000/mm^3 or absolute neutrophil counts above 5,000/mm^3 or elevated

erythrocyte sedimentation rate or procalcitonin level[18] all are associated with increased risk for pneumococcal bacteremia and all have poor predictive values. These tests are best used as negative predictors because a WBC count below 10,000/mm^3, normal absolute neutrophil count, or a normal erythrocyte sedimentation rate have negative predictive values that are near 99 percent.

The clinical significance of "occult" bacteremia in untreated children has been of considerable interest and debate because some have argued "occult" bacteremia is the prologue to serious pneumococcal disease and others believe it is primarily a self-resolving syndrome of less significance. Observational studies demonstrate spontaneous clearance in approximately one third of patients and persistent signs or symptoms of illness in as many as two thirds of patients.[288]

Persistent bacteremia, even in those with persistent clinical illness, is not common even in the absence of antimicrobial therapy. However, the development of focal, presumed pneumococcal infection is not uncommon (Table 85-5).[528] Temperature greater than 39°C (102.2°F) at follow-up best correlates the presence of persistent bacteremia or a new focus of infection. Persistent bacteremia and new focal infections were associated with higher temperature (mean of 38.8°C vs. 37.7°C [101.8°F vs. 99.9°F]), greater elevation in WBC count (18,900/mm^3 vs. 14,900/mm^3), age younger than 20 months, and no antibiotic treatment being prescribed during the initial visit.[38] Complications such as meningitis, pneumonia, cellulitis, periorbital cellulitis, and AOM are the most common focal infections reported at follow-up. Children in whom a lumbar puncture was performed at the initial presentation with fever without a focus, at the time of pneumococcal bacteremia as reflected by a positive culture of blood, have been reported to have a fivefold greater risk for having CSF pleocytosis and meningitis at follow-up.[584]

TABLE 85-5 **Outcome in Children with Pneumococcal Bacteremia Initially Managed at Home**

Outcome	No. of Children	Percent
Antimicrobial therapy at first visit	46	47
Improved at second visit	37	79
Not improved at second visit	9	20
Persistent bacteremia at second visit	2	4
Meningitis at second visit	2	4
No antimicrobial therapy at first visit	51	53
Improved at second visit	16	31
Not improved at second visit	35	69
Persistent bacteremia at second visit	13	25
Meningitis at second visit	2	4

From Teele DW, Marshall R, Klein JO. Unsuspected bacteremia in young children: a common and important problem. *Pediatr Clin North Am* 1979;**26**:773–84.

The role of antibiotics in initial management of the febrile child at risk for bacteremia for the prevention of serious focal complications is controversial. Bachur and Harper reported higher rates of persistent clinical illness, persistent bacteremia, and focal infection in those not treated at visit during which the blood culture was drawn compared with children receiving oral or parenteral therapy at initial visit.[38] He also identified that only one of eight patients with meningitis at follow-up returned prior to notification of a positive blood culture, suggesting the practice of blood culture at initial visit enhances the early identification of at-risk children prior to clinical progression of disease, at least in some children. Whether this syndrome is unique to the United States or industrialized countries or is universal including developing countries is unclear, largely because of differences in clinical practices in performing blood cultures in ambulant febrile children. The syndrome of "pneumococcal bacteremia without a focus" represents 61 to 70 percent of IPD in the United States.[596]

Comparable to reports from the United States, bacteremia without a focus, defined as a positive blood culture with no obvious focus after clinical and laboratory evaluation, was identified in 179 (70.5%) cases at a Canadian hospital in Alberta.[310] Forty percent of those admitted to the hospital and 89 percent of those not admitted to the hospital did not have a focus of infection. Twenty-nine percent of patients had focal infection; 8 percent had meningitis, almost 10 percent had pneumonia, 5.5 percent had periorbital cellulitis, and 6 percent had other clinical syndromes. Few cases were identified in the first 90 days of life, with the majority occurring in children between 3 and 36 months of age. Comorbid illness, primarily cardiac, respiratory, and neurologic conditions, was present in 21.6 percent of hospitalized children compared with 3.8 percent of those managed as outpatients. The overall mortality was low, 0.7 percent. In other industrialized countries, primarily Europe, a low proportion of IPD is characterized as bacteremia without a focus (18% to 20%). In developing countries the proportion is even lower (~1%).[311,400,485]

Reports from cities such as Bangkok suggest that the "benign" nature of bacteremia without a focus is not a universal observation. In a hospital-based study in Bangkok, IPD without a focus was associated with 23 percent mortality, which was especially high in children with comorbid conditions.[495] These reports suggest that the syndrome, IPD without a focus, is different in severity and associated complications in Thailand compared with that described in the United States and Canada, with a large proportion of patients developing pneumonia or meningitis and with high death rates during the initial few days of hospitalization. Earlier age at onset, nutritional status, comorbid conditions, or genetic factors may result in a different syndrome with more rapid progression of pneumococcal bacteremia and reduced likelihood of spontaneous clearance than the slower progression and relatively high rate of spontaneous resolution described in U.S. children. Yildirim and colleagues reported that during the years 2007 through 2009, bacteremia without

any focus was the most common clinical presentation among children younger than 24 months of age (46.9% of all cases), whereas the majority of the cases in children older than 24 months of age had bacteremic pneumonia (45.9%).[593]

Pneumococcal Sepsis with Purpura

Sepsis, characterized by hypotension and even purpura that mimics meningococcemia, is also reported with pneumococcemia (Fig. 85-14). It has been observed most often in children with sickle-cell anemia as well as in asplenic children, although it has also been reported in children with immunodeficiency as well as on rare occasion in otherwise healthy children. Unlike meningococci, pneumococci do not produce an endotoxin. However, pneumococcal autolysin has been proposed as a potential mechanism. This glycan-teichoic acid fragment released from the bacterial cell wall has produced purpura when injected to monkeys and mice.[93,220]

Acute hemorrhagic edema in association with pneumococcal sepsis has also been described, possibly suggesting a vasculitic mechanism.[372]

Pneumococcal Meningitis

Streptococcus pneumoniae has become the most common bacterial cause of bacterial meningitis in most countries after the introduction of Hib conjugate vaccines, as well as the falling incidence of meningococcal disease in North and South America and Europe, in part as a result of meningococcal C conjugate vaccine programs. Although meningitis is a less common presentation of IPD in children compared with bacteremia, sepsis, and pneumonia, the case-fatality rates are high (6% to 54%) and neurologic morbidity frequent in survivors (0% to 50%).[201,417] Traditional signs and symptoms of bacterial meningitis including lethargy/unconsciousness, neck stiffness, a bulging anterior fontanelle, and reduced feeding are each individually associated with increased risk for meningitis at presentation.[570] The duration of illness prior to presentation can be quite variable. A proportion of children, estimated at 20 percent, have abrupt onset of signs and symptoms.[65] In others, meningitis presents after several days of illness and precise determination of the onset of meningeal signs is challenging. Seizures develop in approximately a fourth of patients. Decreased consciousness and septic shock occur in 11 and 16 percent, respectively.[25]

FIGURE 85-14 ■ *Streptococcus pneumoniae* sepsis with purpura fulminans in a child who had undergone splenectomy for refractory idiopathic thrombocytopenic purpura. (See companion Expert Consult website for color version.) (From American Academy of Pediatrics. Pneumococcal infections. In: Pickering LK, editor. *Red book: 2012 report of the Committee on Infectious Diseases*. Elk Grove Village, Ill.: American Academy of Pediatrics; 2012, p. 571–82.)

Examination of CSF for the presence of bacteria by microscopy and culture yields a bacterial etiology in more than 70 percent of children who have not as yet received antimicrobial therapy.[201] Antigen-detection assays, such as latex agglutination and now PCR assays, enhance the identification of a bacterial pathogen and are of most value in those children who received antimicrobial treatment before performance of the lumbar puncture.[280] PCR assays can also effectively identify pneumococcal serotypes in CSF samples, especially when patients have already been started on antibiotic therapy.[88] The mean total CSF WBC count varies but in general is greater than 1000 WBC/mm^3.[473] The CSF protein level is generally increased, and the glucose value is often extremely low. Recent analysis suggests that patients are unlikely to have pneumococcal meningitis if all of the following criteria are absent: (1) positive CSF Gram stain, (2) CSF absolute neutrophil count of at least 1,000 cells/mm^3, (3) CSF protein of at least 80 mg/dL, (4) peripheral absolute neutrophil count of at least 10,000 cells/mm^3, and (5) a history of seizure before or at the time of presentation.[388]

Prolonged fever, lasting more than 10 days, or recurrence of fever after initial defervescence is reported in pneumococcal meningitis.[65] In such children a repeat lumbar puncture may often reveal minimal pleocytosis. Most often, an alternative diagnosis of a nosocomial infection is found in children with recurrent fever. Diagnoses such as viral infection, phlebitis, urinary tract infection (especially in children requiring catheterization), and drug fever are common. Occasionally, complications of pneumococcal infection such as subdural effusion, complicated pneumonia with effusion, endocarditis, or pericarditis may be the source.[121] When dexamethasone has been administered as part of the initial management, a fever spike after defervescence can occur after discontinuation.[421,432] Relapse of the meningitis has been reported rarely as the cause for prolonged or secondary fever.[121] There does not appear to be any increased morbidity or mortality in children with recurrent or prolonged fever.[148] The outcome and long-term complications

of pneumococcal meningitis include severe hearing loss, seizures, learning or mental difficulties, or paralysis.[25] Patients with pneumococcal meningitis have a higher mortality rate and are at greater risk for the development of neurologic sequelae than are patients with *N. meningitidis* or *H. influenzae* type b infection.[274,387] The mortality rate varies from 6.3 to 20 percent, with the highest mortality in the youngest children.[476] A peripheral WBC count of less than 5000/mm^3 at initial evaluation was recognized as a poor prognostic factor with a high mortality rate.[297] A trend toward a higher mortality rate also was noted if the CSF WBC count was less than 1000/mm^3. A similarly poor outcome can be predicted in patients with pneumococcal meningitis when low CSF glucose concentrations (<1.11 mmol/L)[165] or high CSF protein concentrations (>250 mg/dL)[297] are present. A multicenter U.S. study reported a 7.7 percent mortality rate, with 25 percent of children suffering neurologic morbidities and 32 percent with moderate or severe hearing loss.[25]

Children who have cochlear implants are more than 30 times more likely than healthy children to acquire pneumococcal meningitis, presumably from direct extension from the nasopharynx or middle ear. Implants with positioners were associated with a greater risk than those without. The risk period for development of pneumococcal meningitis appears to extend for 24 months after implantation.[53,443] Delayed sterilization of CSF cultures after antimicrobial treatment also has been associated with a poorer outcome.[314] In children with delayed sterilization, a statistically greater proportion had hearing loss at 1 year and more children had neurologic abnormalities, although these differences were not statistically significant.

Higher incidence rates, greater case-fatality rates, and more frequent neurologic sequelae have been observed in children from developing countries compared with those from industrialized countries. Case-fatality rates in excess of 50 percent have been reported from some African and Asian countries and included results from studies performed during the late 1990s and early 2000s.[83,400,409,453,467] The case-fatality rates from pneumococcal meningitis in developing countries and indigenous native populations in fact exceed the overall annual incidence rates of pneumococcal meningitis in industrialized countries by 15-fold to 100-fold.[506] The in-hospital case-fatality rates provide a minimal estimate as to the true mortality associated with pneumococcal meningitis, as indicated by studies with follow-up beyond the hospitalization period. A study in The Gambia showed that 23 percent of hospital survivors subsequently died in the community mainly related to neurologic sequelae resulting from the meningitis.[570] Late clinical presentation of cases to the hospital as well as delays in diagnosing meningitis (e.g., 22% initial erroneous misdiagnosis of pneumococcal meningitis as malaria in Malawi[367]) may contribute to this high mortality. The review by Peltola reported that mortality rates for pneumococcal meningitis (45%) were greater than for *H. influenzae* (29%) or *N. meningitidis* (8%).[417] A meta-analysis on mortality due to bacterial meningitis in developed countries also found higher mortality rates associated with pneumococcal meningitis (15.3% vs. 3.8% for *H. influenzae* type b and 7.5% for *N. meningitidis*).[46]

Pneumonia

Defining pneumococcal pneumonia in children remains a challenge because a specific pathogen cannot be documented in most cases unless bacteremia or empyema occurs. Vaccine probe studies have helped to redefine the spectrum of clinical pneumonia associated with *S. pneumoniae* and extended the clinical description beyond lobar pneumonia. Lobar pneumonia remains the classic pulmonary disease resulting from pneumococcal infections. High fever exceeding 40°C (104°F), general fatigue, a productive cough, and dyspnea are the prototypical presenting signs and symptoms. In older children, chest pain is often associated with a lobar infiltrate. Fever and cough are nearly universal, occurring in 90 and 70 percent, respectively. Severe abdominal pain is often a presenting symptom in left lower lobe disease, chest pain occurs in 10 to 50 percent of patients,[524] and meningeal signs may be present with apical infiltrates, especially in young children. Comparison of pneumococcal pneumonia with respiratory syncytial virus disease demonstrates significant overlap in presentation. Children with pneumococcal pneumonia less often have tachypnea but more often high WBC counts (mean of 20,800/mm^3 in pneumococcal pneumonia) and high CRP level (mean of 137 mg/L). Alveolar infiltrates are observed more frequently, but not exclusively, in pneumococcal pneumonia.[270] Children with bacteremic pneumococcal pneumonia were more ill appearing than children with nonbacteremic pneumococcal pneumonia. Lobar infiltrates on chest radiographs were present in the majority of bacteremic cases. Pleural effusion is common and occurs in as many as 40 percent of patients; however, only 10 percent have substantial fluid accumulation and 2 percent develop empyema.[326] Patients with pleural fluid secondary to pneumonia have the usual signs and symptoms, with chest pain, abdominal pain, egophony, and/or dullness on percussion. A pleural friction rub, abdominal pain, and dullness on percussion may also be present. Persistent fever, lasting as long as 3 weeks, can be associated with even relatively small effusions.[524] Several studies have reported *S. pneumoniae* as the most common cause of empyema in children.[82] It was most commonly reported in children between 3 and 5 years of age. Serotypes 1, 19A, and 3 were the most common pneumococcal serotypes identified in children with empyema.[81]

Establishing the diagnosis of a specific pathogen in children with pneumonia remains challenging. Blood culture is positive in no more than 10 percent of patients with pneumococcal pneumonia.[567] Children with bacteremic pneumococcal pneumonia usually have a high temperature and leukocytosis on admission, with peripheral WBC counts exceeding 15,000/mm^3, similar to those without bacteremia.[533] Based on vaccine probe studies, Madhi and colleagues reported that procalcitonin and CRP were equally useful in children infected and not infected with HIV to improve the specificity of the

pneumococcal pneumonia efficacy end point in the vaccine trial among children with radiologically confirmed pneumonia.[339]

No strict radiologic definition of pneumococcal pneumonia in children is accepted broadly. At one end is the typical appearance of severe lobar consolidation (Fig. 85-15), which is recognized as associated with bacterial pneumonia.[585] At the other end are the mild interstitial and perihilar changes that are often associated with viral infections or asthma and that may be part of the spectrum of normal appearances for children in developing countries. In studies performing lung aspiration in cases of radiologically proven lobar infiltrates, the proportion of patients in whom *S. pneumoniae* was detected was high.[150,559,563] *S. pneumoniae* was the predominant bacterial pathogen in most studies of children with lobar infiltrates (Table 85-6).[338] The role of the pneumococcus in children with lobar infiltrates is further supported by the observed 63 percent reduction in pneumonia with alveolar infiltrates in children vaccinated with a 7-valent pneumococcal conjugated vaccine compared with children receiving placebo.[57]

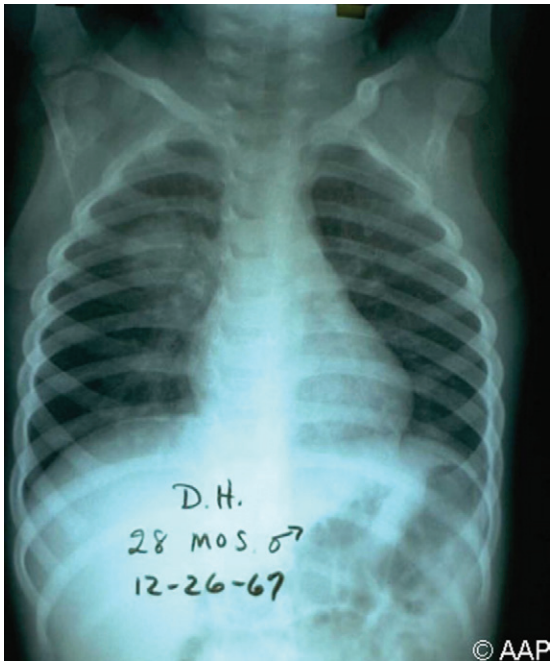

FIGURE 85-15 ■ Segmental (round) pneumococcal pneumonia in 28-month-old child. (See companion Expert Consult website for color version.) (From American Academy of Pediatrics. Pneumococcal infections. In: Pickering LK, editor. *Red book: 2012 report of the Committee on Infectious Diseases.* Elk Grove Village, Ill.: American Academy of Pediatrics; 2012, p. 571–82.)

Although the role of the pneumococcus in children with lobar consolidation is known (see Table 85-6), its role in cases with other radiologic findings is not as well defined. Studies demonstrating a reduction in hospitalizations associated with "viral pneumonia" in children immunized with PCV suggest a role for the pneumococcus in disease manifesting as interstitial and perihilar infiltrates, at least in countries such as South Africa. A recent study found that the incidence of human metapneumovirus (hMPV) lower respiratory tract infection was reduced by 45 percent and the incidence of clinical pneumonia was reduced by 55 percent in non-HIV-infected children who had received three doses of conjugate pneumococcal vaccine. In fully vaccinated HIV-infected children, the incidence of hMPV-associated lower respiratory tract infection was reduced by 53 percent and that of clinical pneumonia by 65 percent.[340]

In the preantibiotic era, the natural course of pneumococcal pneumonia consisted of 7 to 9 days of a stationary phase of symptoms followed by worsening of the systemic signs ("pre-crisis") and high mortality. In those who recovered, defervescence, sweating, polyuria, and a brief febrile attack ("post-crisis") were observed.[31,404] Today, the mortality rate in industrialized countries is extremely low (<1%), even in cases of bacteremic pneumonia, and long-term complications are uncommon.[276] However, hemolytic-uremic syndrome in association with pneumococcal pneumonia and bacteremia is being reported with increasing frequency. Thirty-seven cases occurring between 1997 and 2009 in North America were recently reported from the Emerging Infection Network.[44] In general, the patients were severely ill and presented with pneumonia and bacteremia, and half of the patients required mechanical ventilation and chest tube placement or video-assisted thoracoscopic surgery. Ninety-two percent of cases were associated with

Modified from Madhi S, Pelton SI. Epidemiology, diagnosis and treatment of serious pneumococcal infections in children from pneumococcal vaccines. In: Siber GR, Klugman KP, Makela PH, editors. *The impact of conjugate vaccine.* ASM Press; Washington, DC, 2008, p. 95–108.

PCV13 serotypes, with serotype 19A recovered from half of the children. Twenty cases have been reported from Taiwan.[315]

Otitis Media

Twenty-five to 60 percent of cases of AOM are attributable to the pneumococcus. The bacteriologic outcome of *S. pneumoniae* AOM is less favorable than is the outcome of AOM caused by other organisms when untreated or treated inappropriately.[289,380,402] The pathogenesis is thought to reflect recently acquired colonization in combination with viral respiratory tract infections in most cases.[527,543] Some studies have suggested that pneumococcal AOM is more severe than that caused by other pathogens; however, the overlap in signs and symptoms prevent clinical criteria alone from accurately predicting the etiologic pathogen. Observations from 1970 support that pneumococcal AOM is accompanied more frequently by great pain and higher fever than was AOM caused by other pathogens; it also is more purulent, as characterized by higher middle ear fluid white blood cell counts, and the tympanic membrane is more erythematous.[75,236] Subsequent studies have reported that when *S. pneumoniae* is recovered from the nasopharynx at the time acute otitis media is present there are greater abnormalities in the tympanic membrane, as reflected in higher severity score and greater likelihood of persistent symptoms on day 5, persistence of tympanic membrane abnormalities on day 28, and recurrence before day 28. Spontaneous remission of the infection occurs less commonly in patients with pneumococcal AOM than in those with other pathogens.[235] Tympanic membrane perforation is also more commonly observed with pneumococcal otitis.

Mastoiditis

Acute mastoiditis was the most common complication of otitis media and occurred in as many as 20 percent of untreated cases. Although now dramatically decreased since the routine use of antimicrobial therapy, it still remains the most common suppurative complication of AOM.[107] *S. pneumoniae* is the most common cause of acute mastoiditis in children and accounts for 25 to 46 percent of all culture-proven cases.[186,234] Increased cases of mastoiditis due to multidrug-resistant *S. pneumoniae* have been reported after the introduction of PCV7 in the United States.[403] Recent studies of the incidence of mastoiditis suggest a higher rate of disease in countries in which observation is the first-line approach to children with otitis media; however, the risk still remains remarkably small in such countries.[549]

Sinusitis

Studies suggest that 5 to 10 percent of all upper respiratory tract infections are complicated by bacterial sinusitis when defined as either acute, febrile illness with facial swelling (usually localized to the eye) or initial improvement in signs and symptoms and then recurrence of signs and symptoms or persistence of rhinorrhea, low-grade fever, and facial swelling without improvement beyond 10 days.[561] *S. pneumoniae* is the pathogen most commonly isolated from patients with sinusitis, and it causes 35 to 42 percent of all bacterial cases.[562] Clinical signs and symptoms are often age dependent and related to the maturation of the different sinuses affected. Ethmoidal and maxillary sinuses are most commonly involved, especially in children younger than 5 years old. Sinusitis is manifest initially as a viral infection, followed by a nasal discharge that frequently is purulent and accompanied by cough. The symptoms are often increased at night with accumulation of secretions from postnasal drip. Malodorous breath is frequent.[246] In cases of sinusitis, isolation of *S. pneumoniae* from the nasal discharge strongly suggests its involvement at the site of infection.

Conjunctivitis

Purulent bacterial conjunctivitis due to *S. pneumoniae* is well described, with nonencapsulated strains most often involved. Clinically, bilateral, purulent discharge is the most common clinical presentation and often distinguishes it from viral disease.[59,182,560,573] When conjunctivitis is present with acute otitis media, the so-called conjunctivitis-otitis syndrome, *H. influenzae* is the most common pathogen.[62]

In a study in Minnesota, children with conjunctivitis were evaluated in two cities.[80] Forty-nine percent of positive cultures showed *S. pneumoniae*. All isolates were nontypeable. Pulsed-field gel electrophoresis identified three clonal groups, with 84 percent of the isolates belonging to one clonal group. Multilocus sequence typing revealed that isolates had the same multilocus sequence type as that of isolates from a 2002 pneumococcal disease outbreak at a New England college. It has been suggested that certain pneumococcal strains have a predilection for causing conjunctivitis.[80] These reports suggest that pneumococcal conjunctivitis can be highly contagious in school settings.

Bone and Joint Infections

Septic arthritis caused by *S. pneumoniae* is a relatively rare condition that accounts for 2.2 to 9.7 percent of all cases.[205,463] Its main initial clinical features are single or multiple swollen, warm, and painful joints. The joints most commonly involved are the knee and the ankle.[248] In one study, the mean duration of symptoms before hospitalization was 2 days, and patients were hospitalized for an average of 11 days. The mean peripheral WBC count was 20,600/mm^3, the erythrocyte sedimentation rate usually was greater than 90 mm/hr, and the CRP concentration generally was higher than 100 mg/L. *S. pneumoniae* can be isolated from synovial fluid or blood in most patients.[463] The outcome is favorable in the majority of cases unless underlying diseases or sepsis occur concomitantly.[248]

Soft Tissue Infections

S. pneumoniae has become an uncommonly recognized etiologic agent of soft tissue infections but can cause

serious infections. Most commonly, facial cellulitis has been described in otherwise healthy children in conjunction with recovery of *S. pneumoniae* from either local or systemic cultures.[130] Periorbital infection can be a complication of sinus disease and can uncommonly spread to the orbit, resulting in orbital cellulitis or abscess manifested as proptosis and ophthalmoplegia.[486] Most patients with such complications are younger than 3 years of age and previously were healthy. Fever and peripheral WBC counts higher than 15,000/mm^3 can be observed in most patients, and blood cultures frequently are positive. Overall, response to therapy generally is good, and patients usually recover.[187] In patients with connective tissue diseases such as systemic lupus erythematosus, HIV infection, or corticosteroid treatment, pneumococcal cellulitis has been reported and may be severe.

Peritonitis

Primary peritonitis, where the pathogen travels from the blood or via the lymphatic system to the peritoneal cavity, is an uncommon condition that accounts for only 17 percent of all cases of peritonitis. *S. pneumoniae* is the major pathogen in primary peritonitis, responsible for 38 percent of all cases.[192] Primary pneumococcal peritonitis should be considered in the differential diagnosis of children with an acute abdominal syndrome,[169] particularly in children with nephrotic syndrome, immunocompromised status, or sickle-cell disease.[192] Colonization of the perineum and subsequent spread via the fallopian tube to the peritoneal cavity have been suggested as the pathogenesis of primary pneumococcal peritonitis and is consistent with the observation that 87 percent of cases occur in females.[483,496] Most of the patients are between 4 and 10 years of age.[483] Symptoms include diffuse abdominal pain, fever, vomiting, and diarrhea. Abdominal tenderness can be maximal in the right lower quadrant, which can lead to confusing it with acute appendicitis. In some cases, *S. pneumoniae* can be isolated as the only cause of peritonitis secondary to appendicitis. Cultures should include blood, peritoneal fluid, and a vaginal swab. Some patients need laparotomy or laparoscopy to exclude other pathologic processes such as appendicitis or a tuboovarian abscess.[496] Morbidity and mortality rates can be high when the period without treatment exceeds 1 week, but in most cases the outcome is favorable when treated adequately.[483]

Endocarditis

S. pneumoniae endocarditis, including that caused by nonpenicillin-susceptible strains, is most often reported to involve the aortic and mitral valves.[492] The syndrome of pneumococcal meningitis, pneumonia, and endocarditis was previously more common. It was initially described by Osler but is also known as Austrian syndrome. This triad is now uncommon, and *S. pneumoniae* accounts for less than 3 percent of cases of bacterial endocarditis currently.[249,376,525] This triad is rarely present in children. In children, mitral valve involvement has been described most often. A history of congenital heart disease is common. Medical therapy alone has a high mortality rate that was improved in a group of patients receiving combined medical and surgical interventions.[94]

Pericarditis

In the preantibiotic era, pneumococcal pericarditis was a relatively frequent complication of lobar pneumococcal pneumonia and the most common pathogen in purulent pericarditis in children. After the introduction of antibiotics, the pneumococcus declined as a cause of pericarditis, decreasing from 51 to 9 percent of cases and occurring mainly in adults. Currently, infections of the pericardium are rare in children and often are related to underlying medical conditions such as immunodeficiency.[419]

Infection in Immunocompromised Hosts

Patients with functional asplenia, including those with hemoglobinopathies, are at high risk for IPD. In 19 asplenic patients with IPD, the clinical findings included fever (86%), shock (27%), petechiae or purpura (27%), disseminated intravascular coagulopathy (18%), and respiratory distress (18%). Clinical illness included bacteremia alone (52%), meningitis (26%), bacteremia with otitis/sinusitis (13%), and bacteremia with pneumonia (9%). The mortality rate was 32 percent.[478]

HIV-infected children with pneumonia usually have the typical symptoms of fever, shortness of breath, and productive cough associated with pleuritic pain. The chest radiograph shows unilobar or multilobar infiltrates, and peripheral WBC counts often are elevated. A comparison between HIV-infected and non-HIV-infected children with community-acquired pneumonia showed no significant differences between groups with regard to the duration of hospitalization and mortality rates.[342] In contrast, when only patients infected with isolates belonging to the traditional "pediatric serotypes" were compared a higher rate of pneumonia with or without concurrent meningitis in the HIV-infected group was observed. Recurrence of pneumococcal infection within 6 months from the initial episode is also common in patients infected with HIV, particularly children.[176] Most HIV-infected patients recover without significant sequelae, and the clinical course of their systemic infection does not appear to be markedly different from that in healthy children.[259]

Patients with immunodeficiency disorders consisting of antibody and complement deficiencies are at high risk for acquisition of invasive and recurrent pneumococcal infection.[259] Children with nephrotic syndrome have a particularly increased risk for the development of pneumococcal peritonitis, mainly during relapse of their renal disease.[154] Children with sickle-cell disease are prone to the development of overwhelming *S. pneumoniae* bacteremia and sepsis; in children younger than 3 years of age, the incidence of bacteremia is 6.1 events per 100 patient-years, and the case-fatality rate is 24 percent for *S. pneumoniae* sepsis.[597]

S. pneumoniae is an important pathogen in patients undergoing bone marrow transplant (BMT) or periph-

eral blood stem cell transplant (PBSCT), with two patterns of disease recognized. Early onset is observed in both allogeneic and autologous BMT and PBSCT patients within the first 35 days. Later-onset disease occurs after 100 days and is more frequent in allogeneic compared with autologous BMT and is the most common bacterial infection in such patients. Functional hyposplenism secondary to irradiation, chronic graft-versus-host disease, and decreased IgG2 antibody contribute to the risk for IPD and the poor outcome. Case-fatality rates approximate 20 percent.[303] Chronic graft-versus-host disease is associated with long-term risk for pneumococcal infections in recipients of BMTs.[143,303]

Solid-organ transplant patients are at increased risk for pneumococcal disease. The risk varies with the nature of the transplant, but recipients have a lifelong increase in risk owing to the immunosuppressive therapy required for transplant survival, and recurrent disease is common. Of 42 children who had undergone bone marrow or solid organ transplantation and became infected with *S. pneumoniae*, 8 (19%) had recurrent pneumococcal infections.[479] Solid-organ recipients were more likely to have recurrent invasive disease than were recipients of BMTs. Death occurred in 2 of 42 recipients (5%). Cardiac transplant patients have an incidence of 39 cases of IPD per 1000 patients per year,[509] the highest risk for which occurs in African American heart transplant recipients who undergo transplantation because of idiopathic dilated cardiomyopathy.

TREATMENT

The pneumococcus is the causative bacterial agent in many respiratory and invasive infections, many of which are often treated empirically. Empirical and pathogen-directed treatment guidelines are available for the major disease syndromes associated with pneumococcal infection. In the absence of rapid methods for diagnosis of disease and identification of drug-resistant strains, empirical treatment will continue to be the rule in clinical practice.

Dosing regimens and susceptibility of β-lactam and non-β-lactam antimicrobial agents used to treat pneumococcal infections are shown in Tables 85-7 and 85-8, respectively.[253] Dosing regimens are shown as total recommended daily dose and number of doses per day and should be used in conjunction with local prescribing information. Susceptibility data reflect overall findings from U.S. and international studies, and local susceptibility data should be taken into consideration because susceptibility patterns may vary considerably.

Pneumonia

Guidelines for the management of infants and children older than 3 months of age with presumed bacterial community-acquired pneumonia have been published by the Pediatric Infectious Diseases Society and the Infectious Diseases Society of America.[69] These guidelines recommend no antibiotic treatment for a preschool-aged child with relatively mild disease because many of these infections are likely to be viral and the patient will not benefit from antibiotic therapy. Children with mild disease severity should be considered for outpatient treatment with antibiotics, with amoxicillin and amoxicillin-clavulanate recommended as first-line agents and cefpodoxime, cefuroxime, cefprozil, levofloxacin, and linezolid as alternatives. For children who do not have clinical, laboratory, or radiographic evidence that distinguishes bacterial from atypical pneumonia, a macrolide can be added to the β-lactam antibiotic. Hospitalization is required for any child requiring intravenous therapy, hydration, or respiratory support. For inpatient treatment of children fully immunized with conjugate pneumococcal and Hib vaccines, parenteral ampicillin, penicillin G, ceftriaxone, or cefotaxime is recommended, with the addition of clindamycin or vancomycin if community-acquired methicillin-resistant *S. aureus* is suspected. Except for ampicillin and penicillin G, the same agents are recommended for children who are not fully immunized. If atypical pneumonia cannot be excluded from the differential diagnosis, addition of azithromycin is recommended, with doxycycline and levofloxacin alternatives for older children. Other agents approved for treatment of pneumococcal pneumonia in adults include linezolid, tigecycline, and ceftaroline, a cephalosporin with anti-methicillin-resistant *S. aureus* activity.[263]

Sinusitis

Although fewer than 2 percent of cases of acute viral rhinitis are complicated by acute bacterial rhinosinusitis (ABRS), patients with symptoms lasting more than a week or increasing in severity after 5 to 7 days can have bacterial superinfection that requires treatment with antimicrobial agents. The most common cause of ABRS is *S. pneumoniae*.[95] Treatment guidelines suggest treating pediatric patients with mild disease and no antibiotic exposure in the previous 4 to 6 weeks with amoxicillin-clavulanate at 45/6.4 mg/kg/day.[95] Patients with type I β-lactam hypersensitivity can be treated with levofloxacin, whereas those with non–type I hypersensitivity can be treated with clindamycin plus either cefixime or cefpodoxime. Patients with more severe disease, recent antimicrobial use, or failure of initial therapy should be treated with amoxicillin-clavulanate at 90/6.4 mg/kg/day, clindamycin plus either cefixime or cefpodoxime, or levofloxacin. Ampicillin-sulbactam, ceftriaxone, cefotaxime, or levofloxacin is recommended for children with severe infection requiring hospitalization.

Acute Otitis Media

AOM is the most commonly treated bacterial infection in children. It most often occurs between age 6 months and 3 years and usually follows a viral respiratory tract infection. As in other respiratory infections, *S. pneumoniae* (25% to 50% of cases) and *H. influenzae* (23% to

TABLE 85-7 **Dosing Regimens and Susceptibility of β-Lactam Antimicrobial Agents Used to Treat Pneumococcal Infections***

Antimicrobial Agent	*Total Daily Dose (No. of Doses per Day)*		Susceptible Breakpoint (μg/mL)†	Percent Susceptibility
	Adolescents	Infants and Children		
Parenteral Agents—Meningitis				
Penicillin G	24 million units (6-8)	300,000-400,000 units/kg (4-6)	≤0.06	63.5
Ampicillin	12 g (6)	300 mg/kg (4)	Penicillin ≤0.06	68.3
Ceftriaxone	4 g (1-2)	100 mg/kg (1-2)	≤0.5	82.2-86.2
Cefotaxime	8-12 g (4-6)	225-300 mg/kg (4-6)	≤0.5	87.4
Cefepime	6 g (3)	150 mg/kg (3)	≤0.5	85.3

67%) predominate as causes.[14] The incidence of AOM initially decreased after the introduction of PCV7 in 2000 but subsequently increased, associated with increases in antimicrobial resistant serotypes such as serotype 19A.[86] The introduction of PCV13 in 2010 is likely to reverse this trend.[513]

According to the practice guidelines published by the American Academy of Pediatrics and the American Academy of Family Physicians Subcommittee on Management of Acute Otitis Media, initial observation for 24 to 72 hours with necessary analgesia is acceptable to ascertain a diagnosis of probable bacterial AOM.[14] Once

diagnosis is certain, initial treatment should be with either amoxicillin 80 to 90 mg/kg/day or, in case of high temperature (>39° C) or severe otalgia, amoxicillin-clavulanate 90/6.4 mg/kg/day. In a recent study of children 6 to 24 months old with no history of recurrent AOM and with bona fide AOM for whom clinical outcomes were assessed by validated otoscopists, 10 days of high-dose amoxicillin-clavulanate (80 mg/kg/day amoxicillin in two divided doses) or cefdinir (14 mg/kg/day in two divided doses) was significantly more effective than 5 days of cefdinir (86.5% vs. 71.0%; $p = .001$) as therapy for AOM.[87]

Bacteremia

S. pneumoniae is a common cause of bacteremia in children and is frequently associated with pneumonia. Treatment guidelines follow recommendations for treatment of pneumonia.[95,253]

Meningitis

After PCV7 introduction, an estimated 3330 pneumococcal meningitis hospitalizations and 394 deaths were prevented in persons of all ages during 2001 through 2004 in the United States, and pneumococcal meningitis is now more common in adults than in children.[538] An estimated 4100 cases and 500 deaths from bacterial meningitis occurred annually in the United States during 2003 through 2007, with 58 percent due to *S. pneumoniae.*[532] Practice guidelines for the management of bacterial meningitis recommend the following.[210] Patients suspected of having meningitis should have lumbar puncture and blood cultures performed as soon as possible, with empirical antimicrobial therapy begun immediately afterward. For infants and children 6 weeks of age and older, dexamethasone should be considered as adjunctive therapy. The issue remains controversial, but, if used, dexamethasone should be administered concurrently with the first dose of antibiotics. Initial empirical treatment for patients older than 1 month is vancomycin plus a third-generation cephalosporin such as ceftriaxone or cefotaxime. Treatment can be adjusted once culture and susceptibility results are obtained. Penicillin breakpoints specific for meningitis have recently been established: for susceptible disease, less than or equal to 0.06 μg/mL and for resistant disease, greater than or equal to 0.12 μg/mL.[98]

PREVENTION

Nonimmunologic Strategies

This category includes interventions that aim at (1) reducing risk factors predisposing to the development of pneumococcal infection, (2) providing chemical substances (e.g., antibiotics) to abort or prevent pneumococcal colonization or disease, and (3) modifying anatomic abnormalities that predispose to the development of pneumococcal infection.[290]

A factor that is important not only for pneumococcal infection but also for many other serious bacterial infections is the need to improve general health and nutrition worldwide, particularly in developing countries. Many risk factors for the acquisition of pneumococcal infection that can be alleviated include poor living conditions, overcrowding, poor hygiene, malnutrition, and a high prevalence of viral infections, particularly respiratory viruses, measles, and HIV infection. In the developed world, carriage of pneumococci, especially antibiotic-resistant strains that result in sporadic infections as well as outbreaks, is related to daycare attendance and is proportional to the number of children per group.* Therefore, reducing the number of children per group in daycare centers and developing alternative forms of childcare may reduce the rate of pneumococcal morbidity.

The importance of passive smoking (namely, being in close contact with smokers in the same household) has been highlighted as a risk factor for the development of pneumococcal disease.[393] Thus, efforts to prevent smoking in the home may have an important role in the prevention of pneumococcal infection. Breast-feeding may protect against some infections related to *S. pneumoniae*, such as otitis media.[19,77,135,457,543] Therefore, breast-feeding should be encouraged, especially in families in which otitis media occurs commonly, although the precise role of prolonged breast-feeding in protecting against pneumococcal infection has not been established.

Antimicrobial chemoprophylaxis is used predominantly for two indications: prevention of recurrent AOM and prevention of pneumococcal sepsis in children with anatomic or functional asplenia. Data now exist to support the common practice of prescribing regular doses of penicillin for children with asplenia or sickle-cell disease.[174] Chemoprophylaxis is used commonly for the prevention of middle ear infections. Controlled clinical trials have compared antimicrobial chemoprophylaxis with placebo, surgery, or historical controls.[60] Various antibiotics were tested (either as ongoing daily prophylaxis or as intermittent treatment during viral infections). Most of the studies, but not all, showed a benefit of chemoprophylaxis over controls, especially for amoxicillin, ampicillin, sulfonamides, and trimethoprim-sulfamethoxazole. However, those studies were performed before both the era of increased antibiotic resistance in *S. pneumoniae* and the use of pneumococcal conjugate vaccines. The dosing schedule recommended for prophylaxis usually is half the daily therapeutic dose given once a day, but the optimal dosing regimen has not been defined.

The potential benefits of otitis media chemoprophylaxis have been weighed against the ability of chemoprophylaxis to alter the nasopharyngeal flora, foster colonization with resistant organisms, and thereby compromise the long-term efficacy of the prophylactic drug and contribute to the propagation of resistant organisms throughout the community. As a result, the practice of otitis media chemoprophylaxis has been reduced greatly. In one study, prophylaxis with amoxicillin induced a dramatic increase in the carriage of penicillin-resistant *S. pneumoniae*, as well as increased carriage of other resistant pathogens.[76] The fear of increasing resistance led the Committee on Infectious Diseases of the American Academy of Pediatrics to issue a warning against the widespread use of otitis media prophylaxis and to state that "Antimicrobial prophylaxis should be reserved for control of recurrent acute otitis media, defined by 3 or more distinct and well-documented episodes during a period of 6 months or 4 or more episodes during a period of 12 months." Surgical otitis media prophylaxis by insertion of tympanostomy tubes or adenoidectomy (with or without tonsillectomy) has been recommended for otitis-prone children.[288] Some authorities now prefer this modality to the chemoprophylactic approach because it is not associated with altered flora. However, surgical risks also need to be considered.

A novel approach to prevention of pneumococcal disease is the potential for use of oligosaccharides to prevent attachment of organisms, including *S. pneumoniae*, to the respiratory mucosa. Because colonization of the respiratory mucosa can result in local and systemic disease, as well as spread to other individuals, prevention of colonization is a reasonable approach to prevent disease. Human milk oligosaccharides can prevent attachment of *S. pneumoniae* and other organisms to the mucosa of the respiratory tract[587,603] and have been shown to interfere with the establishment and progression of experimental pneumococcal pneumonia in infant rats.[244] Natural oligosaccharides act as decoys in mucosa (also in saliva, tears, urine, sweat, and breast milk) and bind the carbohydrate-binding proteins of the microbial pathogens and thereby prevent mucosal attachment.[290] Despite this promise, a large-scale study examining the efficacy of such an oligosaccharide (3-sialyllacto-*N*-neoteratose) given intranasally as prophylaxis for AOM and nasopharyngeal carriage of bacteria failed to show any beneficial effect on either outcome.[544]

Other experiments conducted in Finland showed that xylitol (a five-carbon sugar alcohol used extensively as a sweetener in toothpaste, chewing gum, and various foods) inhibited the growth of streptococci, including *S. pneumoniae*, in vitro.[295,296,541,542] Whether this approach eventually will develop into a practical strategy to prevent respiratory tract infections caused by *S. pneumoniae* and other organisms is not clear. The concept of reducing nasopharyngeal colonization and thereby the number of episodes of bacterial respiratory tract infection through competitive inhibition is novel, and additional agents, altered doses, and alternative methods of administration should be studied.[418]

Immunoprophylaxis

Unconjugated Capsular Polysaccharide Vaccines

Efforts to prevent pneumococcal infection by providing specific immunity started more than 100 years ago, as described at the beginning of this chapter. It is well established that both passive immunization by administration of specific antibodies and active immunization with polysaccharides can provide protection against many pneumococcal infections.

Passively administered serotype-specific antibodies can protect animals and humans against diseases caused by pneumococci, with administration of antisera associated with improved clinical outcome, including reduced mortality, in humans.[84] Human immunoglobulins can prevent experimental pneumococcal bacteremia in mice[96,462] and otitis media in chinchillas.[489] The finding of low cord blood IgG antibodies, mainly of the IgG1 subset, is predictive of early-onset AOM in infancy.[48,330,468] In several clinical studies, bacterial polysaccharide immune globulin (BPIG) obtained by immunizing healthy adults with a 14-valent pneumococcal vaccine (in addition to group C meningococcal and Hib polysaccharide vaccines) decreased the prevalence of AOM[491] and invasive infection[491] in children. High-dose BPIG administered to infant rats resulted in high serum concentrations of serotype-specific IgG against serotype 3 with protection against nasopharyngeal carriage of this serotype.[347]

Immunization with pneumococcal polysaccharide antigens, mainly in adults, has been studied for a long time. First, hexavalent polysaccharide vaccines were introduced in the late 1940s, followed by 14-valent vaccines in the late 1970s and 23-valent vaccines in the early 1980s. The last, produced by several manufacturers, contains 25 μg of purified, nonconjugated polysaccharide antigens per dose for serotypes 1, 2, 3, 4, 5, 6B, 7F, 8, 9N, 9V, 10A, 11A, 12F, 14, 15B, 17F, 18C, 19A, 19F, 20, 22F, 23F, and 33F. These 23 serotypes accounted for approximately 90 percent of the serotypes responsible for IPD in all age groups in both developed and developing countries.[216,217,450,502] The 23-valent polysaccharide vaccines are tolerated well by healthy children for primary[316,482] or repeated immunization.[67] However, the presence of preexisting antibodies was associated with an increased incidence of adverse events at the site of infection.[61,299,396]

In general, these bacterial polysaccharide-based vaccines are poorly immunogenic in infants and toddlers for important disease-causing serotypes, which is to be expected because bacterial capsular polysaccharides induce antibody production primarily by T-cell-independent mechanisms that still are not fully developed in this age group.[446] Polysaccharide-specific IgG concentrations are relatively high in very young infants because they are acquired transplacentally and consist mainly of IgG1. Nasopharyngeal colonization with various serotypes of *S. pneumoniae* results in the natural production of serotype-specific antibodies.[79,221,531,582] The immune response to pneumococcal polysaccharides is serotype dependent, and some serotypes commonly associated with disease are especially poor immunogens until children reach the age of approximately 5 years.[133] Serotypes 6A, 6B, 12, 19A, 19F, and 23F are examples of this phenomenon.* The IgG subclasses that are produced after exposure to polysaccharide antigens of other bacterial species are mainly IgG2 and IgG4.[327] A second dose of polysaccharide vaccine does not provide a booster effect and even may result in a reduced immune response when compared with the response after the first dose, which may suggest an antigenic tolerance effect.[61,394,553] Children with many underlying conditions that predispose to the development of pneumococcal infection often respond more poorly to pneumococcal polysaccharide vaccines than do otherwise normal children. Published studies of children with recurrent respiratory tract infections all have demonstrated this phenomenon.†

In addition to a relatively poor systemic immune response, the polysaccharide vaccines have been shown to induce only minimal mucosal immune responses. Serotype-specific antibodies to pneumococcal serotypes 6A, 14, 18C, and 23F were measured in the sera and middle ear effusions of 14 children who had received a 14-valent pneumococcal capsular polysaccharide vaccine and in control subjects.[298] Serotype-specific antibody concentrations in middle ear effusions correlated with serum concentrations and generally were higher in pneumococcal vaccine recipients than in control vaccine recipients. IgM class antibodies frequently were seen only in the serum samples, thus suggesting that antibodies diffuse into the middle ear space rather than being synthesized in situ in response to the vaccine. This finding refutes previous theories that local production of antibodies occurs in the middle ear after vaccination.[300,497,498]

Limited data exist regarding the efficacy of polysaccharide pneumococcal vaccines in preventing disease in infants and children. A large study conducted in Papua New Guinea on more than 7000 children showed a reduction in mortality rates from acute lower respiratory tract disease.[317,447,448] In this study the effect was dramatic: a 59 percent reduction in mortality rates in all children vaccinated (5 months to 5 years of age) and a 50 percent reduction in children vaccinated before they reached 2 years of age. However, the vaccine did not protect against nonfatal disease. In the United States, researchers have suggested that the polysaccharide vaccines would be 62 percent effective in preventing IPD caused by vaccine serotypes in children aged 2 to 5 years.[159]

The effectiveness of polysaccharide pneumococcal vaccines in preventing otitis media is not clear. Several studies have shown some reduction in the incidence of otitis media in vaccinated children.‡ No effect of the use of polysaccharide pneumococcal vaccine on pneumococcal nasopharyngeal carriage could be demonstrated.[111,114] These studies on T-cell-independent polysaccharide pneumococcal vaccines clearly show that their benefit in children is at best marginal and limited to the minority of serotypes that are immunogenic in this age group.

Conjugated Capsular Polysaccharide Vaccines

The conjugation of pneumococcal polysaccharides to protein alters the immune response by recruiting T cells that both amplify the B-cell response and create memory B cells, in contrast to the T-cell-independent nature of the immune response that occurs after the administration of bacterial polysaccharides (Fig. 85-16).* These polysaccharide-protein antigens elicit protective antibody in infants and prime the immune system for future boosting with reexposure to either alone or conjugated. Antibodies elicited by polysaccharide-protein conjugates demonstrate improved functional capacity (determined by avidity and opsonization assays), persist, and result in a booster response with reexposure.[146] The concept of conjugation technology, demonstrated to be highly successful with capsular polysaccharide from *H. influenzae* type b, was modified to permit development of vaccines with multiple polysaccharides while maintaining immunogenicity for each individual polysaccharide. Currently, vaccines with 7 to 13 different conjugated pneumococcal polysaccharide antigens are licensed and next-generation vaccines with even greater numbers of polysaccharides are in clinical trials.[305]

Table 85-9 shows pneumococcal conjugate vaccines that are licensed in at least one country, are being tested in phase III efficacy studies, or are in advanced phase II (safety and immunology) stages. The selection of serotypes for inclusion in the various formulations is based on serotype epidemiology discussed earlier in this chapter. These conjugate vaccines were developed primarily targeting serotypes responsible for IPD, including meningitis, bacteremic pneumonia, and empyema.

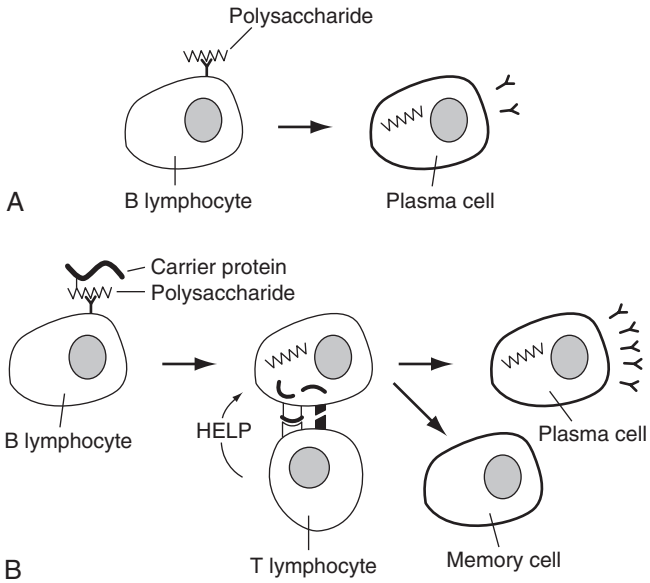

FIGURE 85-16 ■ T-cell-independent (**A**) and T-cell-dependent (**B**) antibody responses to polysaccharide or polysaccharide-protein conjugate antigens. (From Eskola J, Anttila M. Pneumococcal conjugate vaccines. *Pediatr Infect Dis J* 1999;**18**:543–51.)

The primary target population for polysaccharide conjugate vaccines is infants and toddlers because disease incidence is highest, global mortality substantial, and polysaccharide vaccines demonstrated to be poorly immunogenic and of limited value. Pneumococcal conjugate vaccines have been shown to be immunogenic, safe, and well tolerated, with vaccine reactions primarily being local, including pain, redness, and swelling at the injection site. The incidence of fever and irritability was

*References 35, 138, 279, 451, 490, 507.

somewhat higher than reported in studies with Hib conjugate vaccines or hepatitis B vaccines, perhaps because the pneumococcal vaccines represent 7 to 11 separate monovalent vaccines administered together as opposed to the monovalent Hib conjugate vaccine or hepatitis B vaccine. The 7-valent pneumococcal vaccine conjugated to CRM_{197} protein (PnCRM7) was found to be safe even when administered to low-birth-weight and preterm infants.[487]

PCV formulations were demonstrated to elicit high concentrations of IgG1 subclass antibodies, functional antibody in opsonophagocytic assays, and antibody with high avidity.[146,153] The immunogenicity of one formulation (PnCRM7) was demonstrated to be immunogenic in children with sickle-cell disease,[391,396,553] HIV infection,[6,286,287,385] solid-organ transplants,[329] allogeneic and autologous bone marrow transplants,[21,143] as well as in Alaska Natives and American Indians.[360] A 9-valent CRM (PnCRM9) pneumococcal vaccine also was immunogenic in children with sickle-cell disease.[189]

Clinical trials were used to evaluate the efficacy of the various pneumococcal conjugate vaccine formulations across a spectrum of end points and populations. The end points believed to be of most importance in evaluating these vaccines have been (1) prevention of IPD as defined by isolation of pneumococci from a normally sterile site (e.g., from blood, CSF, aspirates, and biopsy specimens); (2) prevention of mucosal infections such as otitis media, sinusitis, and nonbacteremic pneumonia; and (3) reduction of nasopharyngeal colonization, which in turn results in herd immunity due to reduced transmission of organisms.

Three efficacy studies of conjugate vaccines with the end point of a reduction in the number of invasive infections were completed by mid-2002, two with PnCRM7 and one with the PnCRM9 vaccine. The first study was a prospective double-blind study of 37,868 healthy infants in northern California to whom either the PnCRM7 vaccine or a control vaccine was administered at 2, 4, 6, and 12 to 15 months of age.[56] The vaccine was 97.4 percent efficacious (95% CI, 82.7% to 99.9%) against invasive disease caused by the seven serotypes included in the vaccine in fully vaccinated infants and 93.9 percent efficacious (95% CI, 79.6% to 98.5%) in partially vaccinated infants. No evidence of an increase in invasive disease caused by serotypes that were not included in the vaccine was detected, and thus the overall effect was a reduction in total IPD by 89.1 percent (95% CI, 73.7% to 95.8%). This trial led to U.S. licensure of the vaccine in February 2000, with subsequent licensure in many other countries. Additional analysis has shown that the vaccine was as effective in the subset of low-birth-weight and premature infants as it was in the full study cohort.[487] Secondary analyses demonstrated reductions in all-cause pneumonia and AOM.

A second large-scale efficacy study with the PnCRM7 vaccine was conducted among American Navajo and White Mountain Apache children in the United States using a cluster randomization strategy in which communities rather than individuals are randomized. This population has rates of IPD that are approximately five times those of the general U.S. population.[395] In this double-blind, community-randomized study, infants and young children aged 2 months to 2 years received the PnCRM7 vaccine or a control vaccine. A total of 8292 infants from 43 communities were enrolled; of these, 8091 lived in 38 communities that were randomized to the pneumococcal or the control vaccine. During the study period, two cases of IPD caused by the serotypes included in the vaccine occurred in the vaccine group versus eight in the control group. After controlling for community randomization, the primary efficacy of the vaccine was 76.8 percent (95% CI, 9.4% to 95.1%), and the intent-to-treat efficacy was 86.4 percent (95% CI, 11% to 96.1%).

A third efficacy study was conducted with the PnCRM9 vaccine among black infants in South Africa. In this double-blind, randomized, placebo-controlled study, PnCRM9 was administered to children at the ages of 6, 10, and 14 weeks according to the World Health Organization's Expanded Programme on Immunization. The infants were monitored until they reached 2 years of age, and the study was completed by the end of 2001. The intent-to-treat analysis showed a reduction of 82.5 percent (95% CI, 39.0% to 96.7%) in the number of invasive infections caused by the serotypes included in the vaccine for children not infected with HIV and a reduction of 65.4 percent (95% CI, 23.8% to 85.7%) in antiretroviral-naïve children infected with HIV.[294]

Once this vaccine was licensed in the United States (February 2000), universal immunization for children younger than 2 years of age and selected immunization for high-risk children was implemented. The Committee on Infectious Diseases of the American Academy of Pediatrics recommended routine administration as a four-dose series for infants at ages 2, 4, 6, and 12 to 15 months (known as the 3+1 schedule); catch-up immunization was recommended for all children up to 23 months of age. The PCV7 vaccine could be given along with other age-appropriate childhood immunizations in a separate syringe and at a separate injection site. Infants of very low birth-weight could be immunized when they reached a chronologic age of 6 to 8 weeks, regardless of their calculated gestational age. The PCV7 vaccine also was also recommended for all children younger than 60 months of age at high risk for acquiring IPD, including patients with sickle-cell disease, asplenia, HIV infection/acquired immunodeficiency syndrome, diabetes, cancer, liver disorders, lung diseases, and cardiac diseases. For some high-risk children, administration of PPV23 was recommended for supplemental protection. The only contraindication to receiving the vaccine was a serious allergic reaction to a previous dose of this vaccine or one of its components. Children with minor illnesses such as colds could be vaccinated.

The incidence of IPD decreased sharply in infants and toddlers after the widespread use of PCV7 in U.S. children.[55,239,577] Effectiveness studies demonstrated a rapid decline in IPD owing to vaccine serotypes in children younger than 5 years of age (Fig. 85-17) within 2 years of vaccine introduction, with a further gradual decline that persisted through 2010, when a second-generation pneumococcal conjugate vaccine was introduced (PCV13).[424,593] Rates of bacteremia without a focus,

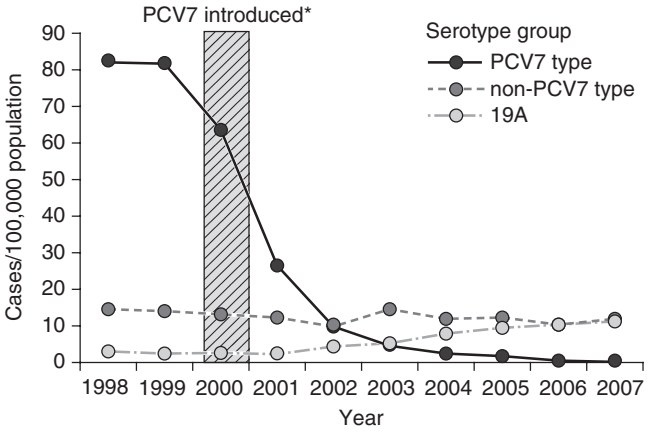

FIGURE 85-17 ■ Changes in IPD in U.S. children younger than 5 years of age by serotype groupings. PCV7 serotypes include 4, 6B, 9V, 14, 18C, 19F, and 23F. (From Pilishvili T, Lexau C, Farley MM, et al; Active Bacterial Core Surveillance/Emerging Infections Program. Sustained reductions in invasive pneumococcal disease in the era of conjugate vaccine. *J Infect Dis* 2010;**201**:32–41.)

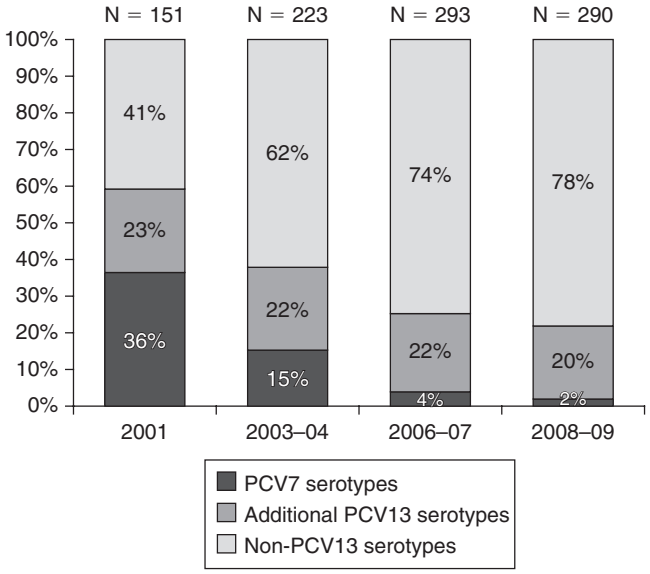

FIGURE 85-18 ■ Percent of pneumococcal isolates within each sampling period by vaccine serotype grouping. PCV7 serotypes are 4, 6B, 9V, 14, 19C, 19F, and 23F. Additional 13 valent serotypes are 1, 3, 5, 6A, 7F, and 19A. Non-PCV13 serotypes are all other serotypes. (From Wroe PC, Lee GM, Finkelstein JA, et al. Pneumococcal carriage and antibiotic resistance in young children before 13-valent conjugate vaccine. *Pediatr Infect Dis J* 2012; **31**:249–54.

meningitis, and bacteremic pneumonia all declined. By 2006 to 2007, PCV7 serotypes accounted for only 2 percent of IPD cases in children compared with 83 percent prior to 2000. By 2009, nasopharyngeal PCV7 serotypes comprised only 2 percent of pneumococcal isolates carried in the nasopharynx of children younger than 6 years of age (Fig. 85-18).[589] Despite the decline in carriage of PCV7 serotypes, overall pneumococcal carriage did not change as a result of increases in carriage of non-vaccine serotypes, particularly serotypes 19A, 15A, 15B, 15C, 6C, 23A, 23B, and 35B. These changes in serotype distribution resulted in reduced transmission of PCV7 serotypes and a decline in IPD due to vaccine serotypes in all age groups, including infants younger than 90 days of age and too young to be protected directly, as well as adults.[427] In fact, Simonsen noted that 90 percent of the reduction in pneumococcal disease mortality occurred though herd immunity among adults 18 years and older (Table 85-10).[494] Consistent with the observed differences in virulence between pneumococcal serotypes as discussed earlier, the current belief is the increase in "replacement" serotypes is primarily associated with serotypes with a lower capacity to produce disease after colonization. However, some of the serotypes, specifically 19A and 7F, are associated with modest increases in invasive disease both in children and adults. By 2007, the incidence of IPD due to serotype 19A had increased from 2.6 cases per 100,000 to 11.1 per 100,000 in children younger than 5 years of age and represented nearly 40 percent of all IPD in this age group (Fig. 85-19).[593]

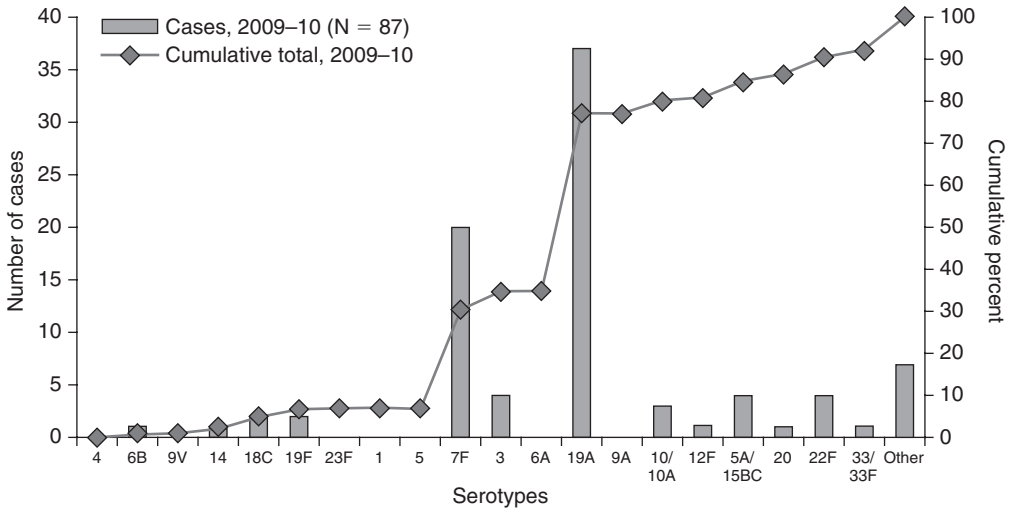

FIGURE 85-19 ■ Serotypes causing invasive pneumococcal disease in children younger than 18 years of age in Massachusetts between October 31, 2009, and September 1, 2010. (From Yildirim I, Stevenson A, Hsu KK, et al. Evolving picture of invasive pneumococcal disease in Massachusetts children: a comparison of disease in 2007-2009 with earlier periods. *Pediatr Infect Dis J* 2012;**31**:1016-21.)

PCV13 was introduced in 2010 in the United States for healthy children through age 5 years, children with chronic illness through age 6, and children 6 through 18 with sickle cell disease, HIV infection, and other high-risk conditions. Proportionally, PCV13 serotypes comprised nearly 75 percent of all IPD in children younger than 18 years of age, with 19A disease representing nearly 40 percent (see Fig. 85-19). The most recent reports from multiple U.S. surveillance programs[275,369,592] demonstrate further declines in IPD in children younger than 5 years of age and a decline in disease due to serotype 19A. PCV13 was introduced in the United Kingdom early in 2010, and a decline in IPD has been reported due to PCV13 unique serotypes.[362]

Global experience with PCV7 demonstrated similar observations with dramatic declines in IPD due to vaccine serotypes, initially in immunized children and then subsequently in unimmunized adults, despite the fact that alternative vaccine schedules (to 3+1) were employed in many countries. The United Kingdom and parts of Canada introduced a schedule of two primary doses with a booster dose at 12 months of age, whereas Australia introduced a schedule of three primary doses without a booster (a 3+0 schedule).[125,363,265] These schedules proved to be effective in both reducing IPD in children as well as creating indirect protection in unimmunized populations despite evidence that a primary two-dose series results in less serum antibody for serotypes 6B and 23F.[278,331]

PCV10 was introduced, adding serotypes 1, 5, and 7F to the seven serotypes in PCV7. Jokinen reported on the early effectiveness of PCV10 against IPD in Finnish children. A dramatic decline in vaccine serotype IPD among children 6 to 11 months of age was observed.[269]

Although invasive infections are the most dramatic part of the pneumococcal disease spectrum, respiratory tract infections such as otitis media are far more frequent.[325] Efficacy studies have shown protection against AOM due to vaccine serotypes in children immunized with pneumococcal conjugate vaccines. In one study, PnCRM7 vaccine reduced the number of clinically diagnosed otitis media episodes by 7 percent (95% CI, 4.1% to 7.9%).[160] The effectiveness of the PnCRM7 vaccine against frequent otitis media was 9.3 percent (95% CI, 3.0% to 15.1%) when three episodes in 6 months or four in 12 months were counted and 22.8 percent (95% CI, 6.7% to 36.2%) when a frequency of five episodes in 6 months or six in 12 months was considered. Children who received the vaccine were 20.1 percent (95% CI, 1.5% to 35.2%) less likely to require placement of a pressure-equalizing tube than control subjects. Otitis media was not a primary outcome measure in this study, and the efficacy of the vaccine against otitis media caused by vaccine serotypes could therefore only be determined on children with spontaneously draining ears; a 66 percent calculated efficacy against disease caused by vaccine serotypes was found in this group.

A second study, conducted in Finland, looked at the efficacy of PnCRM7 vaccine against pneumococcal AOM caused by vaccine serotypes as well as overall episodes.[147] The clinical diagnosis of AOM was based on predefined criteria, and bacteriologic diagnosis was based on culture of middle ear fluid obtained by myringotomy. The children were monitored through 24 months of age. The efficacy of the vaccine in reducing AOM caused by vaccine serotypes was 57 percent (95% CI, 46% to 67%). The point estimate for efficacy of the vaccine in reducing all culture-confirmed pneumococcal AOM was 34 percent. The vaccine was not effective against nonvaccine pneumococcal serotypes, except against serotype 6A. The vaccine also was ineffective against otitis media caused by *H. influenzae* and *Moraxella catarrhalis*, and the overall high protection provided against the serotypes included in the vaccine was offset partially by an increase in the number of episodes of otitis media caused by other serotypes of pneumococci and other pathogens. The overall reduction in the number of episodes of AOM of any cause in the pneumococcal vaccine group was 6 percent.

Although this difference did not reach statistical significance, it was similar to the 7 percent reduction in AOM observed in the California study.[56] In addition, similar to the California Study by the time children reached the age of 4 to 5 years, tympanostomy tube placement was reduced 39 percent compared with control subjects.[408]

A third study was conducted by the same Finnish group, in parallel with the study just described, with a different 7-valent vaccine (serotypes 4, 6B, 9V, 14, 18C, 19F, and 23F conjugated to the meningococcal outer-membrane protein complex [OMPC]-PnOMPC7).[282] This vaccine was administered in four doses at 2, 4, 6, and 12 months of age. At 12 months of age, approximately 22 percent of the PnOMPC7 conjugate vaccine recipients received a nonconjugate 23-valent polysaccharide vaccine as a booster while the others received a fourth dose of PnOMPC7. The efficacy of the vaccine in reducing the number of cases of otitis media caused by the serotypes included in the vaccine was 56 percent, with 25 percent for reduction of any pneumococcal AOM. However, there was no overall reduction in the number of episodes of otitis media, with nonvaccine serotype pneumococci and other pathogens producing replacement disease.

Another study, using an 11-valent PCV (the prototype for PCV10), conjugated to outer membrane protein D of nontypeable *H. influenzae*, demonstrated a similar magnitude of protection against vaccine serotype AOM despite a markedly different study design.[433] Because the 11-valent PCV was conjugated to protein D from nontypeable *H. influenzae*, a 35 percent reduction in AOM episodes due to this pathogen was also reported, with an overall reduction in all episodes of AOM of approximately 33 percent. Further studies confirming the efficacy of PCV10, where some serotypes are conjugated to protein D, are pending completion.

Since licensure and universal immunization of children younger than age 2 with PCV7, several studies have shown that the reduction in AOM exceeds that reported in clinical trials.[202,426,564,602] Several hypotheses have been proposed to explain the observation. First, with widespread immunization and dramatic reduction in nasopharyngeal carriage of vaccine serotypes, effectiveness against vaccine serotypes will increase to nearly 100 percent. Second, prevention of early episodes of pneumococcal AOM will change the natural history of AOM in children, reducing subsequent episodes.[163] Pneumococcal AOM is now primarily caused by nonvaccine serotypes.[511,512]

Reports of AOM and mastoiditis unresponsive to antimicrobial therapy requiring drainage and systemic antimicrobial therapy due to multidrug-resistant serotype 19A have increased.[403,422] Because PCV13 includes the capsular polysaccharide from 19A, it is expected that such cases will diminish with decreasing prevalence of 19A nasopharyngeal colonization.

Because most cases of pneumococcal pneumonia are nonbacteremic, the role of *S. pneumoniae* can best be demonstrated indirectly in vaccine probe studies by determining the proportion of disease reduction after vaccine implementation. In the northern California PnCRM7 vaccine study, 3711 clinically diagnosed episodes of pneumonia were identified by the age of 3.5 years.[57] The efficacy of the vaccine in reducing the incidence of clinical pneumonia (intent-to-treat analysis) was 6.0 percent. For children in whom a chest radiograph was obtained, an 8.9 percent reduction was observed; for those with a positive chest radiograph (defined as parenchymal infiltrates, consolidation, or effusion), a 22.7 percent (95% CI, 8.7% to 34.5%) decline in disease occurred. Because the reduction in pneumonia was a secondary end point, the precision of the decline has some limitations. However, the findings suggest that more cases of clinically and radiologically proven pneumonia in children are caused by *S. pneumoniae* than previously suspected, with the reduction in disease extending beyond the "classic" lobar pneumonia pattern associated with *S. pneumoniae* to cases with non-lobar infiltrates. Comparable observations from South Africa documented a 22.1 percent reduction in children not infected with HIV immunized with PCV9.[294]

Additional supportive evidence that *S. pneumoniae* has an important role in a broader spectrum of respiratory tract infections can be derived from a study in southern Israel involving toddlers aged 12 to 35 months who attended daycare centers.[118] In this study a 15 percent reduction in non–otitis media upper respiratory tract infection was reported. Episodes of lower respiratory tract disease, including bronchiolitis, cough, and pneumonia were reduced. A reduction of 10 percent in the number of days that antibiotics were given for upper respiratory tract infections was achieved, as was a reduction of 47 percent for lower respiratory tract problems in the pneumococcal vaccine group.

Person-to-person spread is the major route of transmission for *S. pneumoniae*. The nonconjugate pneumococcal polysaccharide vaccines do not have a significant effect on carriage of *S. pneumoniae* in children and adults.[114,337] In contrast, the conjugate vaccines have a significant effect on carriage that expands its public health value. Table 85-11 shows selected studies conducted and published documenting the effect of pneumococcal vaccines on carriage of *S. pneumoniae*. Despite variations in the nature of the conjugate vaccines, populations, and the ages at which the vaccines were administered, a significant reduction in carriage of the serotypes included in the vaccine was observed in all studies. In most studies, serotype replacement was observed as the overall pneumococcal colonization remained relatively constant despite the decline in prevalence of vaccine serotypes.

A change in nasopharyngeal colonization is important because it reduces exposure of unimmunized children and adults to these potential pathogens. This reduction has been demonstrated in studies of toddlers attending daycare centers who were vaccinated with a PnCRM9 vaccine or a control vaccine.[110] In this study, the younger siblings of immunized and control children, who stayed home, were monitored. A marked reduction in the incidence of vaccine-type pneumococcal carriage was seen in the young siblings of those who were vaccinated with the PnCRM9 vaccine when compared with siblings of the control children. In a second study, Navajo and White Mountain Apache children younger than 2 years old were randomized according to their community of residence

to receive either PnCRM7 or meningococcus C conjugate vaccine.[361]

A reduction in carriage of vaccine-associated serotypes was found both in infants who lived with a PnCRM7-vaccinated sibling and in those who did not have direct contact with a PnCRM7-vaccinated child but lived in a vaccine community, demonstrating the indirect protective effect of pneumococcal vaccination on those in the household. Because most antibiotic-resistant *S. pneumoniae* strains belong to only a few serotypes that are included in the conjugate pneumococcal vaccines or are related to these serotypes (see the sections on epidemiology and microbiology), conjugate vaccines are expected to reduce disease, carriage, and spread of antibiotic-resistant *S. pneumoniae* and may have an impact on the use of antibiotics. Indeed, in all vaccine studies that evaluated the effect of conjugate vaccines on nasopharyngeal carriage of antibiotic-resistant *S. pneumoniae*, a reduction in carriage of such strains was observed (see Table 85-11).[110,114,116,119,352]

Although invasive infections are the most dramatic part of the pneumococcal disease spectrum, respiratory tract infections such as otitis media and sinusitis occur far more frequently.[325] In a study investigating current estimates of pneumococcal disease burden, clinical outcome, and vaccine efficacy, researchers estimated that for each annual U.S. birth cohort, routine use of a 7-valent vaccine could prevent 12,000 cases of pneumococcal bacteremia and meningitis, 53,000 cases of pneumococcal pneumonia, and more than 1 million clinical cases of otitis media per year.[325] Pneumonia has a greater impact globally than does otitis media or even invasive infections because of its high mortality rate in children in the developing world.[51,204,320] Thus, the protection conferred by the conjugate pneumococcal vaccines with regard to reduction in the number of episodes of otitis media, pneumonia, and other mucosal infections could have an even greater public health impact on the burden of disease than on prevention of invasive infections.

Pneumococcal disease remains a burden on children throughout the globe. In young infants and children, the elderly, and those with serious comorbidities the disease can be deadly. Progress in prevention, both in the development of effective vaccines and in implementation of vaccine delivery programs in developing countries, has exceeded expectations, resulting in decreased incidence of and mortality from IPD, including meningitis and both bacteremic and nonbacteremic pneumonia.[375] The virtual elimination of nasopharyngeal colonization with vaccine serotypes enhances their public health value by reducing transmission of vaccine serotypes from children to adults, thereby reducing overall rates of pneumococcal disease. Vaccine failure is uncommon; Park and colleagues reported only 155 vaccine serotype infections identified by U.S. surveillance systems, with only 25 in fully vaccinated children, suggesting the combination of direct and indirect effects protects infants as well as children with chronic illness from vaccine serotype disease.[410] These findings demonstrate the major reduction in the burden of vaccine serotype pneumococcal disease in children associated with use of conjugate vaccines.

Nevertheless, potential challenges to the successful scenario observed to date are found in the distribution of disease owing to nonvaccine serotypes. The U.S. surveillance program reported a doubling of the proportion of children with comorbidities and IPD, which increased from 3 percent in 1998/1999 to 7 percent in 2007. In Massachusetts, a report noted that 16 percent of children with IPD have comorbidities that proportionally increased with age. Among the 155 cases of vaccine failure referred to previously, a disproportionate proportion were reported to occur in children with comorbidities (37%).[410] Ladhani and colleagues also reported that comorbidities were present in 17.7 percent of U.K. children with IPD

caused by PCV7 serotypes.[306] Case-fatality rates also reflected great vulnerability of children with comorbidities, with mortality from pneumococcal disease (4.4% overall) higher for meningitis (11.0%) and for children with comorbidities (9.1%).

The most commonly reported comorbidities associated with pneumococcal disease include malignancies and immunocompromised conditions.[240] Recent data demonstrate that children with asthma, diabetes, and neurologic disorders such as seizures and muscular dystrophies have increased relative risk for IPD compared with age-matched healthy control subjects.[575] Although the risk is modest with a single comorbidity, it escalates in children with two or more. Certainly the high incidence of both HIV infection and sickle-cell disease in developing countries in Africa is likely to result in these children being at high risk for nonvaccine serotype disease. Children with malnutrition or tuberculosis or exposed to second-hand smoke may also have higher risks for disease owing to nonvaccine serotypes to erode vaccine success that requires ongoing surveillance and analysis.

CONCLUSION

Pneumococcal disease, most notable invasive disease and pneumonia, has decreased considerably, specifically in children in industrialized countries over the past decade in association with the introduction of protein-conjugated polysaccharide vaccines as part of national childhood vaccination schedules. The decline in disease has been larger in unimmunized adults than in immunized children as a result of herd protection created by the reduction in carriage and transmission of vaccine serotypes. In addition, decreases in antimicrobial resistant vaccine serotypes has resulted.

However, in developing countries, acute respiratory tract infections in general and pneumonia in particular remain the leading causes of morbidity and mortality.[357] The mortality rate from respiratory tract infections in developing countries is estimated to be 10- to 30-fold higher than in developed countries.[377,580] Otitis media, although often not perceived as a severe problem in developing countries, may progress to chronic suppurative otitis media and acquired hearing loss in children.[7] Global Alliance for Vaccines and Immunization programs has been critical in reducing the time line for introduction of pneumococcal conjugate vaccine into developing countries.

These advances have been limited by replacement of nasopharyngeal colonization by vaccine serotypes with nonvaccine and frequently antimicrobial-resistant serotypes, resulting in some erosion of vaccine effectiveness as a result of disease with nonvaccine serotypes in IPD and pneumonia as well as other respiratory pathogens in otitis media. These limitations, in turn, have been countered by the introduction of "second generation" vaccines containing additional serotypes. However, because there are currently 93 recognized serotypes, with evolution of additional serotypes in this genetically promiscuous organism likely to continue, development of alternative, broadly conserved vaccine targets would be very beneficial in the long term.[366]

CHAPTER 86

Miscellaneous Gram-Positive Cocci

Randall G. Fisher

The focus of this chapter is on relatively uncommon gram-positive cocci that are of importance because of their unusual antimicrobial sensitivities and increasing recognition as pathogens in hospitalized patients. The reader is referred to a review of these organisms for more details.[19]

LEUCONOSTOC SPECIES

Bacteriology

Leuconostoc spp. are facultatively anaerobic, gram-positive cocci that usually appear in pairs or chains. They are catalase negative, Vogues-Proskauer positive, and leucine aminopeptidase positive. In addition, colonies often are α-hemolytic on blood agar and also may react with group D streptococcal antiserum. These properties are shared by viridans streptococci, with which *Leuconostoc* spp. often are confused.[21] They also may resemble enterococci, except that they are pyrrolidone carboxylyl peptidase negative. Differences include the production of gas from glucose and high-level vancomycin resistance. *Leuconostoc* spp. have been divided into three subclusters[17]; members of the first of these (the *L. mesenteroides* subcluster) are the only ones of human clinical importance. The most common pathogens are *L. mesenteroides*, *L. lactis*, *L. citreum*, *L. paramesenteroides*, and *L. pseudomesenteroides*.

Epidemiology

Leuconostoc spp. are found commonly on plants, especially sugar cane and leafy vegetables. They also are present in

dairy products and wine.[56] They are used in the food industry as starter cultures in food production.[37,69] Studies using culture methods have suggested that, although they occasionally are recovered from vaginal swabs in healthy individuals[60] and from mucosal surfaces in some hospitalized individuals,[30] *Leuconostoc* spp. are not part of the normal human flora.[3] Case reports of pediatric infection began to appear in the 1980s.[14,31,35,53,76]

Pathophysiology

Leuconostoc spp. rarely are pathogenic. Underlying disease states or compromised immune system, gastrointestinal tract disease (especially short-gut syndrome), previous or current antibiotic therapy, venous or gastrointestinal tract access devices, recent invasive procedures, and infancy are thought to be risk factors.[16,18,30,56] In patients with short-gut syndrome, the presence of central venous catheters and disrupted bowel mucosa are likely the most important risks.[22] Frequently, the organisms are isolated as part of a polymicrobial infection after a patient has been treated with vancomycin.[19] Of the first 21 cases reported in the English literature, 12 were in children, 10 of which occurred in patients younger than 1 year old. Documented portals of entry include central lines,[3,31] peritoneal dialysis and urinary catheters,[8] and gastrostomy tubes.[35] A case of nosocomial meningitis apparently caused by frequent lumbar puncture after intracranial hemorrhage has been reported.[32] Contaminated enteral formula also has been implicated.[9,35,51] One outbreak involving 42 patients in Spain was traced to contaminated total parenteral nutrition solution.[4] Occasional sporadic cases without a known risk factor have been described.[14,30]

Clinical Manifestations

Bacteremia, heralded by fever and usually leukocytosis, is by far the most common clinical manifestation of *Leuconostoc* infection. Gastrointestinal disturbances, especially diarrhea, are common manifestations.[3] Infants are prone to emesis. *Leuconostoc* bacteremia, in association with cough and chest radiographic findings consistent with pneumonia, was reported in a child with acquired immunodeficiency syndrome (AIDS).[56] *L. citreum* has been isolated from the lung tissue of a 33-year-old patient with AIDS who also had *Pneumocystis jiroveci* pneumonia.[25] Small necrotic cavities scattered through both lungs were associated with gram-positive cocci in tissue. Patients with associated dental infections,[76] peritonitis,[26] osteomyelitis,[47] and meningitis[14,23] also have been described. Meningitis has been reported in an otherwise healthy 16-year-old patient and in a neonate with fatal infection despite high cerebrospinal fluid (CSF) bactericidal antibiotic titers.[14,23] A nosocomial cluster of five cases of urinary tract infection caused by *L. pseudomesenteroides* (strictly a species of a new genus, *Weissella*)[13] has been reported,[8] as has a cluster of three cases of *Leuconostoc* septicemia in critically ill postsurgical patients.[63] In a series of 20 cases from Taiwan, 19 of the 20 had health care–associated bacteremia. Eleven of the 20 had an underlying malignancy, and the same number had been hospitalized for 30 days or more at the time the diagnosis was made.[42]

Diagnosis

Cultures usually are positive within 24 to 48 hours. Identification of vancomycin-resistant *Streptococcus* should raise the suspicion of *Leuconostoc* infection and prompt additional biochemical studies,[56] including gas production in MRS broth, failure to hydrolyze arginine, and delayed esculin hydrolysis.

Treatment

Treatment with relatively high doses of penicillin or ampicillin frequently is successful in eradicating infection. Many species produce biofilms[43]; when possible, access devices should be removed. Leuconostocs are most sensitive to the primitive β-lactam antibiotics, especially penicillin and ampicillin, although penicillin tolerance is a common finding.[35,72] They also frequently are sensitive to erythromycin, cephalothin, and the aminoglycosides. Leuconostocs are variably resistant to clindamycin and trimethoprim-sulfamethoxazole. Resistance increases with later generations of cephalosporins.[30,72] Leuconostocs are intrinsically vancomycin resistant because their pentapeptide cell wall precursors end in D-Ala-lactate rather than the usual D-Ala-alanine.[29] Vancomycin cannot bind the lactate. This mode of resistance is the same as that possessed by vancomycin-resistant enterococci. However, whereas resistance in enterococci is plasmid derived and transferable, in *Leuconostoc* spp. it is chromosomally mediated, constitutional, and not transferable.

PEDIOCOCCUS SPECIES

Bacteriology

Pediococci also are intrinsically vancomycin-resistant, facultatively anaerobic gram-positive cocci. They appear most characteristically in tetrads on Gram staining, although they may appear in pairs or clusters.[27] The genus name *Pediococcus* is derived from the Greek word *pedium*, which means "plane." This name, therefore, suggests that this is a genus of cocci that grow in a single plane. It is a misnomer, however, because pediococci are the only lactic acid bacteria that divide in two planes.[24] They are catalase and oxidase negative. They do not reduce nitrates, and no gas is produced in MRS broth.[67] They are pyrrolidone carboxylyl peptidase negative.[19] Most isolates react with Lancefield group D streptococcal antibodies.[67] They are leucine aminopeptidase positive, which distinguishes them from *Leuconostoc* spp.[20] They produce white, opaque, nonhemolytic colonies on sheep's blood agar. A new broth medium, a combination of 90 percent Iso-Sensitest broth and 10 percent MRS broth and called LAB susceptibility test medium, has been found to provide optimal support of growth and to yield the most accurate minimal inhibitory concentration values.[40]

Pediococci produce powerful bacteriocins, which are substances that kill other bacteria. The bacteriocins of pediococci are active against other gram-positive organisms in particular[12] but also are active against *Clostridium botulinum* spores,[52] some gram-negative organisms,[68] and *Listeria monocytogenes*. Reports have suggested that some species of *Pediococcus* have antifungal activity[45]; however, this activity in other studies has been found to be present only at low pH and has been attributed to acetic acid in the medium.[7]

Epidemiology

Like leuconostocs and other lactic acid bacteria, pediococci are found on plants, in dairy products, and in alcohol-containing beverages, where certain species are associated with spoilage.[73] They also are used in the formation of silage[37] and as starter cultures for some meat products. They are not thought to be part of the normal flora. They have been isolated from saliva and stool on rare occasion.[61] Although formerly thought to be nonpathogenic, they now are considered rare opportunistic pathogens with minimal virulence.

Pathophysiology

Pediococci rarely are pathogenic. Many cases of blood isolates are found in patients without symptoms of infection or in polymicrobial cultures in which the significance of the isolate could not be assessed adequately.[46] One patient with a clinical picture of septic shock in whom the only organism recovered was *P. pentosaceus* has been reported.[15] Risk factors for bacteremia, with or without symptoms, appear to be the extremes of age, recent abdominal surgery or tube feeding, broad-spectrum antimicrobial therapy, and the presence of severe underlying disease states.[46] However, because the overall number of reported cases is small, the relative risks of these factors are uncertain.

Clinical Manifestations and Diagnosis

Most patients either are asymptomatic or have fever as the only symptom. Six of the first 12 reported cases of *Pediococcus* bacteremia had concomitant pneumonia. Fifty-six percent of adult patients either were receiving tube feeding or had undergone abdominal surgery within 30 days of isolation of the organism.[46] The three reported pediatric cases occurred in infants, and all had underlying gastrointestinal tract anomalies. A 16-day-old infant with congenital jejunoileal atresia had undergone surgical repair just 8 days before being evaluated.[46] Her acute illness was characterized by emesis and a 200-g weight loss. She was afebrile when initially examined. The second patient was a 64-day-old infant with gastroschisis who had undergone two abdominal surgical procedures.[1] His fever reached 38.6°C (101.5°F), and his peripheral white blood cell count was 38,000/mm^3 with a significant left shift. The third patient was a 3-month-old female infant who had undergone surgical repair of gastroschisis on the first day of life.[2] Lethargy, direct hyperbilirubinemia, and a CSF pleocytosis were noted. Blood cultures grew *Pediococcus* spp., and the CSF (obtained after initiation of antibiotics) was sterile. The patient responded to a 21-day course of ampicillin and gentamicin. An adult case of infective endocarditis in a man who had a history of bowel transplantation for short-gut syndrome[36] and a case of persistent bacteremia in a patient with metastatic adenocarcinoma of the gallbladder have been reported[70]; both responded rapidly to therapy with daptomycin.

Pediococci are isolated frequently in localized infections, especially from abdominal sites, but they are virtually always part of a polymicrobial process. The relative importance of pediococci in these sites is difficult to assess. A case of *Pediococcus* bacteremic pneumonia was reported in a previously healthy pregnant woman.[62] Among 31 cases of *Pediococcus* infection submitted to the U.S. Centers for Disease Control and Prevention laboratory, 17 were from blood culture isolates (including two reported cases of endocarditis) and four were associated with urinary tract infections. Other sources included catheter tips, wounds, peritoneal fluid, CSF, lung, and bone.[19]

Diagnosis of infection with pediococci is established by identifying catalase-negative, vancomycin-resistant, gram-positive cocci in the characteristic tetrads. Many pediococci are misidentified initially as *Streptococcus equinus*, *S. constellatus*, or group D streptococcus, not *Enterococcus*. Reported cases of pediococcal infection may, therefore, represent only a fraction of the total number of infections.

Treatment

Pediococci generally are susceptible to penicillin, ampicillin, imipenem, clindamycin, and first- and second-generation cephalosporins. Although both imipenem and penicillin are highly active against pediococci, they do not appear to be bactericidal. Pediococci are moderately resistant to the quinolones, tetracycline,[73] and trimethoprim-sulfamethoxazole.[59] Pediococci, like leuconostocs, are intrinsically resistant to vancomycin. Resistance is not plasmid mediated, nor can it be transferred to other bacteria.[73] Sensitivity to ticarcillin and cefotaxime, when measured by agar dilution, is poor despite large zones of inhibition on disk susceptibility testing.[73] Occasionally, inducible resistance to erythromycin is found, although most isolates remain sensitive. Aminoglycoside sensitivity is variable. Daptomycin appears to be active.

AEROCOCCUS SPECIES

Bacteriology

The genus *Aerococcus* contains at least five species, but only two, *A. viridans* and *A. urinae*, have known clinical significance. In earlier papers, *A. urinae* was referred to as *Aerococcus*-like organism.[11] Aerococci are catalase-negative, nonmotile, gram-positive cocci that appear preferentially in tetrads but sometimes in pairs or clusters. These relatively slow-growing organisms produce

small, well-delineated, translucent, α-hemolytic colonies on blood agar.[10] They also are weakly bile esculin positive and pyrrolidone carboxylyl peptidase negative. They ferment mannose and mannitol.[57] Like enterococci, most aerococci will grow in 6.5 percent salt.[41]

Epidemiology

Aerococci are distributed throughout the world and are contaminants of air and dust.[33] They also have been found on meat, on raw vegetables, and in small numbers on human skin.[6] In hospitals, aerococci have been cultured from all areas, including operating suites and delivery rooms.[38] They also are found in salt water, where they cause a fatal disease in lobsters.[54]

Disease in humans is an uncommon event, and the organism usually is recovered from the bloodstream of patients with infective endocarditis. Most patients are elderly, but infection of infants and neonates also has been reported.[50,54] A rapidly fatal bacteremia has been described in patients with profound neutropenia.[39] Aerococci are agents of urinary tract infection in elderly and institutionalized persons[66]; these organisms can also cause pediatric urinary tract infections and even pyelonephritis, usually in the setting of obstructive uropathy.[44,48]

Pathophysiology

In most circumstances, aerococci are saprophytic. The exact conditions that favor the development of infection have not been elucidated clearly. Some cases of *A. urinae* infection have occurred after genitourinary tract surgery. One case of septic arthritis developed after an elective abortion.[74] Immunocompromised patients are at higher risk, but infection in otherwise well persons has been described.[57] One report of meningitis in neonates found adherence of aerococci to inflammatory cells and suggested a role of as-yet-undefined adhesion factors.[50] Work in laboratory animals also has shown that a protease isolated from *A. viridans* cleaves the hemagglutinin of influenza virus and potentiates both viral replication and disease in mice.[64] In vitro experiments show that the organism forms biofilms and causes platelet aggregation, features that explain why endocarditis is a common manifestation.[65]

Clinical Manifestations

Most cases of *A. viridans* bacteremia have been found in association with signs and symptoms of subacute infective endocarditis. Severe disease requiring valve replacement surgery has been described, but not in pediatric patients.[5] In a recent series of four cases of *A. viridans* infective endocarditis, two of the patients required surgical intervention.[58] *A. urinae* causes urinary tract infection with dysuria and frequency, usually in the absence of fever.[10] *Aerococcus* infection in childhood is an uncommon occurrence. One case of bacteremia in a 1-month-old infant has been reported.[54] The patient had a 2-day history of loose stools, irritability, and drowsiness and on physical examination was noted to have mottled skin, circumoral cyanosis, and agitation. CSF and urine studies were normal, but blood cultures exhibited pure growth of *A. viridans.* No predisposing factors were identified.

Nathavitharana and associates[50] reported three cases of meningitis caused by *A. viridans.* They occurred in a 7-month-old female infant with jerking movements of the extremities, irritability, and a bulging fontanelle; a 5-month-old female infant with fever, decreased appetite, and generalized convulsions; and a 24-month-old girl whose illness was manifested as fever, vomiting, and the neurologic signs of truncal ataxia, flaccidity, and hypoactive deep tendon reflexes. All three patients had elevated CSF white blood cell counts with 55 to 93 percent segmented forms. Remarkably, all these patients had a history of prolonged illness (1 week to 2 months) before being evaluated, in contrast to patients with other causes of bacterial meningitis. No risk factors for infection were identified in any of these patients, who were thought to have normal immune function.

Swanson and colleagues[71] reported a case of penicillin-resistant *A. viridans* bacteremia in an 11-month-old girl receiving prophylactic penicillin for sickle-cell disease. The patient responded clinically to a 10-day course of therapy with cephalosporins.

Bone and joint infections and wound or other localized infections are exceedingly rare occurrences and not distinguishable from similar syndromes caused by more common organisms. However, there are a number of case reports of spondylodiscitis in patients with *A. urinae* bacteremia or infective endocarditis.[49,75]

Diagnosis

Careful observation of both appearance on Gram stain and growth in culture is key to establishing the diagnosis of aerococcal infection. On Gram stain, aerococci resemble staphylococci. On blood agar, they resemble viridans group streptococci. One series revealed that 1 percent of 719 cultures called streptococci actually were aerococci[55]; another study reclassified 3 percent of 168 cultures.[6] In one study of 24 α-hemolytic, nonenterococcal bacterial isolates from urine, standard identification methods were compared with 16S rRNA sequencing and special biochemical profiling. Thirteen of the isolates were aerococci; all were identified correctly by sequencing, but typical procedures failed to differentiate them from nonaerococcal isolates. Ciprofloxacin and trimethoprim susceptibility and the ability to grow at 45°C improved the discrimination of standard testing.[28] In their propensity toward tetrad formation, they mimic pediococci. However, all aerococci are vancomycin sensitive. In their bile esculin hydrolysis and growth in 6.5 percent salt, they resemble enterococci; unlike enterococci, however, aerococci are pyrrolidone carboxylyl peptidase negative and do not form chains.

Treatment

Aerococci generally are sensitive to penicillin, ampicillin, the cephalosporins, chloramphenicol, and the macrolides. They usually are intermediately susceptible or resistant to sulfonamides and aminoglycosides.[6,33] Susceptibility testing for trimethoprim-sulfamethoxazole

appears to be affected by the medium used in the testing.[34] One report suggests that *A. viridans* and *A. urinae* have distinct antibiograms[41]; that is, *A. urinae* is more sensitive to penicillin and resistant to sulfonamides whereas *A. viridans* is more resistant to penicillin and sensitive to the sulfonamides.[6] Individual case reports do not confirm these in vitro observations, and no large clinical trials of antimicrobial susceptibility have been conducted.

Acknowledgments

The author would like to thank Dr. William Gruber and Dr. Thomas Boyce for their invaluable assistance with earlier versions of this chapter.

SUBSECTION 2 *GRAM NEGATIVE COCCI*

CHAPTER 87

Moraxella catarrhalis

Barbara W. Stechenberg

Once thought to be an unimportant commensal organism in the human respiratory tract, *Moraxella catarrhalis* now is recognized as an important pathogen in respiratory tract diseases, particularly otitis, sinusitis, and lower tract disease. The initial paper by Ghon and Pfeiffer[24] published in 1902 described gram-negative cocci in sputum referred to as *Micrococcus catarrhalis*. Since then, the organism has undergone several changes in nomenclature, first to *Neisseria catarrhalis* because of its resemblance to other *Neisseria* organisms. In 1970, in recognition of the contributions of Sarah Branham, the name was changed to *Branhamella catarrhalis*.[11] More recently, that

this organism should be a member of the genus *Moraxella* has become clear; thus, the name was changed to *M. catarrhalis*. With the transition in nomenclature, the last 2 decades have seen a parallel rebirth of this organism as a mucosal pathogen.

MICROBIOLOGY

M. catarrhalis is a gram-negative diplococcus that is morphologically indistinguishable from *Neisseria*. It has a tendency to resist decolorizing.[1] The organism is kidney shaped, with the flat sides abutting each other. The size varies, but it may be larger than meningococcus or gonococcus. However, the resemblance on sputum Gram stain or conjunctival smear to gonococcus can be striking and clinically confusing.

The organism grows well on blood or chocolate agar and forms small, opaque, grayish colonies that are circular and nonhemolytic. They have poor adhesion to the agar surface, on which they act like hockey pucks when pushed over the surface of the agar plate.[17] The use of selective media such as modified Thayer-Martin or TV broth (Müeller-Hinton broth supplemented with trimethoprim and vancomycin) increases the likelihood of recovering *M. catarrhalis* from the complex flora of the mucosal surfaces.

Isolates of *M. catarrhalis* cannot use maltose, glucose, lactose, or sucrose as carbohydrate sources. *M. catarrhalis* is oxidase-positive and produces deoxyribonuclease. Valuable differentiating tests are hydrolysis of DNA and tributyrin. Several rapid tests such as butyrate hydrolysis, Tween 80 hydrolysis, and selective DNase agar have been described.[51,56] Fatty-acid analysis also has been used to identify atypical strains.

The surface of *M. catarrhalis* is composed of outer-membrane proteins, lipo-oligosaccharide, and pili. The organism does not appear to have a capsule, and the role of the pili is not defined well. By using a technique involving the collection of outer membrane vesicles, which are released into the culture medium, and then examining by sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE), Bartos and Murphy[6] identified eight proteins designated outer membrane proteins A through H. The outer membrane protein patterns of strains from diverse geographic and clinical sources were strikingly homogeneous.

Preliminary studies of the lipo-oligosaccharide of *M. catarrhalis* show that it is more antigenically conserved than those of other gram-negative bacteria.[40] One study suggests that the lipo-oligosaccharide is not an adhesin, but its surface charge plays a critical role in the initial stage of attachment to human epithelial cells.[2] Several adhesins have been identified and may be potential candidates for a vaccine.[40]

Restriction endonuclease analysis has been used as an epidemiologic tool to distinguish strains of *M. catarrhalis*. Patterson and associates[43] used the technique to evaluate a nosocomial outbreak and demonstrate the lack of association of other strains. Dickinson and coworkers[16] used a similar technique to study isolates from children with otitis media.

PATHOGENESIS

The ability of *M. catarrhalis* to produce disease, particularly in sequestered areas such as the ear and lung, indicates that this organism possesses virulence mechanisms that allow it not only to grow in these anatomic sites but also to produce pathologic effects. However, a subset of strains of *M. catarrhalis* associated with selected virulence traits resulting in complement inactivation suggests that some strains are more virulent than others.[9,55]

A body of literature concerning the immune response to *M. catarrhalis* and the antigenic composition of this organism has accumulated.[12,13,35] Goldblatt and associates[25] demonstrated that children younger than 4 years old possess immunoglobulin (Ig)G1 and IgG2 that recognize an 82-kDa outer membrane protein exclusively but that older children mount an IgG3 response to a broad range of outer membrane proteins. Faden and colleagues[21] developed a technique to measure opsonic antibody with the use of outer membrane, antigen-coated beads. Convalescent sera opsonized homologous, antigen-coated sera significantly more often than did acute sera.

Unhanand and coworkers[53] used a murine model to study pulmonary clearance of *M. catarrhalis* from infected lungs. They investigated 10 strains and found marked variability in clearance rates and recruitment of phagocytic cells. With this model, Maciver and associates[37] actively immunized animals with the outer membrane vesicles of *M. catarrhalis* and passively immunized animals with rabbit antiserum raised against these vesicles. Both experiments resulted in enhanced pulmonary clearance of both homologous and heterologous strains. The same model has been used to evaluate the role of a large, antigenically conserved protein of *M. catarrhalis* in pulmonary clearance, as well as the role of outer membrane protein B in defense mechanisms of the lung.[31] The contribution of these proteins, as well as lipo-oligosaccharide, in host defense continues to unfold.

Initially thought to be an exclusively extracellular pathogen, *M. catarrhalis* invades multiple cell types. It is present intracellularly in human pharyngeal tissue, a potential reservoir for persistent colonization.[30] The organism forms biofilms, which may contribute to its role in chronic otitis with effusion.[28,29] Colonization of healthy children is characterized by genotypic heterogeneity, virulence gene diversity, and co-colonization with *Haemophilus influenzae*.[57]

EPIDEMIOLOGY

M. catarrhalis is a normal inhabitant of the upper respiratory tract and is recovered exclusively from humans. The rate of colonization is highest in the early years and then declines steadily to less than 5 percent in adult life.[54] Prevalence studies report that as many as 50 percent of children are colonized with *M. catarrhalis*.[33,38] Faden and associates[22] monitored a large cohort of children from birth to 2 years of age. Sixty-six percent became colonized by the time they reached 1 year of age, and 77.5 percent did so by 2 years of age. The frequency of

nasopharyngeal colonization was higher during visits for otitis media than during well-child visits. Otitis-prone children were colonized by 6 months of age. Restriction endonuclease analysis showed marked heterogeneity, with children acquiring and eliminating many different strains over time.[22,43]

Numerous studies have documented the increased prevalence of *M. catarrhalis* as a pathogen in otitis media, either alone or as a copathogen.[33,44] Shurin and colleagues[49] noted that isolation of *M. catarrhalis* from middle ear exudates increased from 6.4 percent between 1979 and 1980 to 26.5 percent between 1980 and 1982. A similar increase in *M. catarrhalis* as a pathogen in sinusitis has been reported.[58] In the pneumococcal conjugate vaccine (PCV7) era, a significantly higher proportion of PCV7-immunized children exhibit nasopharyngeal colonization with *M. catarrhalis*.[45]

Once colonization of the oropharynx occurs, colonization of the tracheobronchial tree may follow, but usually only if other risk factors are operative. In adults, such risk factors include previous cardiorespiratory disease, smoking, use of corticosteroids, use of immunosuppressive agents, malignancy, and intercurrent viral illnesses.[27,56] In children, many cases of pneumonia are associated with a preceding viral illness, prematurity, underlying lung disease, IgG deficiency, or other risk factors.

Nosocomial transmission has been well documented by DNA restriction endonuclease analysis.[14,43] In pediatric intensive care units, endotracheal intubation and frequent suctioning have been identified as risk factors for the development of pneumonia and bacterial tracheitis.[14,20]

Other interesting associations need to be investigated further. Seddon and associates[48] noted that colonization with *M. catarrhalis* occurred more commonly in asthmatic than in normal children. Whether the organism might be a trigger or pathogen in these children remains to be seen. Gottfarb and Brauner[26] found a high carriage rate of *M. catarrhalis* in children with severe persistent cough.

Infection with *M. catarrhalis* exhibits seasonality in both adults and children.[27,49] Infection is much more likely to occur in the winter and spring months.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Otitis media caused by *M. catarrhalis* is indistinguishable clinically from otitis caused by other pathogens, such as *Streptococcus pneumoniae* and *Haemophilus influenzae*. *M. catarrhalis* may be isolated as a single agent or in combination with other organisms. There is some suggestion that otitis caused by this organism may be associated with less fever; a lower likelihood of a red, bulging membrane or perforation; and a lower C-reactive protein level.[40] Mastoiditis is not commonly seen with *M. catarrhalis*.

Because tympanocentesis usually is not performed in routine cases, the exact cause of an episode of acute otitis media generally is not known. One study found that *Moraxella* was an unusual organism as a single agent in children in whom acute otitis media had been treated recently.[29] Nonetheless, in a study of persistent otitis, Pichichero and Pichichero[44] demonstrated *Moraxella* in 7 percent of specimens. The spontaneous resolution rate of *M. catarrhalis* may be high,[4] and this fact should be considered when therapy is planned.

The clinical manifestations of acute sinusitis caused by *M. catarrhalis* are similar to those of other organisms; therefore, selection of antibiotics should be made with consideration of this organism as a potential pathogen.

Lower respiratory tract disease caused by *M. catarrhalis* may have a broad clinical spectrum; however, because sputum samples often are not available in children, many cases documented in the literature have been severe. Berg and Bartley[7] described five premature infants, all younger than 6 months of age, in whom precipitous clinical deterioration developed after 2 to 4 days of a prodrome consisting of cough, tachypnea, and intercostal retractions. They all required assisted ventilation, which is common in young infants with severe pneumonia.[7,14,19] Some cases of *M. catarrhalis* pneumonia have been associated with bacteremia.

Underlying conditions such as leukemia, acquired immunodeficiency syndrome, and trauma have been reported to predispose a patient to the development of infection with *M. catarrhalis*.[38,59] An association with Ig deficiency has been demonstrated in some patients with disease caused by this organism.[12] In adults, *M. catarrhalis* pneumonia occurs more commonly in patients with human immunodeficiency virus infection, malignancy, or chronic lung problems.[25,56] The role of this organism in less severe manifestations probably is limited.[34]

Bacterial tracheitis caused by *M. catarrhalis* has been reported in both immunocompromised hosts and those with normal immune systems.[20]

M. catarrhalis also has been responsible for a wide variety of other infections. Urethritis caused by this organism can be mistaken for infection with *Neisseria gonorrhoeae*.[50] Several cases of conjunctivitis have been reported; when present in the newborn period, *M. catarrhalis* can mimic the ophthalmia neonatorum of *N. gonorrhoeae*.[52] The relationship of neonatal infections to maternal vaginal carriage of *Moraxella* has not been established.[42]

More severe infections with *M. catarrhalis* include meningitis and bacteremia, so this organism should be considered in appropriate circumstances, especially in immunocompromised children.

Children with *M. catarrhalis* bacteremia may have many different manifestations. Some patients have petechial or purpuric rashes, thus rendering the clinical picture indistinguishable from that of meningococcemia. Others have been neutropenic and have required mechanical ventilation.[8] Baron and Shapiro[5] reported two cases of unsuspected bacteremia in children with nonspecific symptoms. Their manifestations were similar to those of children with occult pneumococcal bacteremia. An immunocompetent child with *M. catarrhalis* bacteremia and preseptal cellulitis has been reported.[47]

Meningitis can occur from hematogenous spread of *M. catarrhalis* from the nasopharynx or as a consequence of ventriculoperitoneal shunt placement or surgery.

Rarely, suppurative arthritis has been seen in children and adults.[32,39] Endocarditis is a rare occurrence, as is peritonitis.

TREATMENT

In the past, *M. catarrhalis* was susceptible to all β-lactam antibiotics. In the late 1970s, however, β-lactamase–producing strains of *M. catarrhalis* were isolated in Europe. In the United States, a parallel increase in the frequency of isolation of β-lactamase–producing *M. catarrhalis* has been noted, so it is not unusual for a laboratory to report that more than 90 percent of strains are β-lactamase producers.

The β-lactamases BRO-1, BRO-2, and BRO-3 are of chromosomal origin. BRO-1 is the most common β-lactamase in North American strains.[15] Because of the high prevalence of β-lactamase–producing strains, many laboratories choose not to do any such testing. The β-lactamase inhibitors clavulanic acid, sulbactam, and tazobactam are active against the enzymes produced by *Moraxella*. Most β-lactamase–positive isolates will respond to achievable concentrations of β-lactam/β-lactamase inhibitor antimicrobial combinations, cephalosporins, and cephamycins.[18,23]

Among the oral cephalosporins active against β-lactamase–positive strains of *Moraxella*, the minimal inhibitory concentration increases twofold to fourfold in the presence of the β-lactamase BRO-1 but not the β-lactamase BRO-2; cefixime is more active than are the older cephalosporins.[41] Resistance to tetracycline (by the nontransferable tetB determinant) and erythromycin has been reported, but such resistance is a rare finding.[10,46]

In vitro, *M. catarrhalis* usually is susceptible to ampicillin-sulbactam, amoxicillin-clavulanate, erythromycin, azithromycin, clarithromycin, trimethoprim-sulfamethoxazole, tetracyclines, chloramphenicol, fluoroquinolones (e.g., ciprofloxacin), aminoglycosides, and second- or third-generation cephalosporins, such as cefuroxime, cefprozil, cefpodoxime, cefixime, cefdinir, and loracarbef.[36] Levofloxacin also exhibits good activity against *M. catarrhalis*.[3] The *Moraxella* organism is resistant to clindamycin, vancomycin, and oxacillin.

PREVENTION

Prevention of nosocomial *M. catarrhalis* infection depends on sound practices of infection control, especially with regard to pulmonary toilet. Prevention of other infections with this organism has not been attempted. Development of a vaccine has been hampered by a lack of an animal model.

CHAPTER 88

Meningococcal Disease

Marsha S. Anderson • Mary P. Glodé • Arnold L. Smith

Epidemic meningococcal meningitis was first described by Gaspard Vieusseux in Geneva in the spring of 1805. In a monograph entitled "The Disease Which Raged During the Spring of 1805," he wrote:

> *It commences suddenly with prostration of strength, often extreme: the face is distorted, the pulse feeble. There appears a violent pain in the head, especially over the forehead; then there comes pain of the heart or vomiting of greenish material, stiffness of the spine, and in infants, convulsions. In cases which were fatal, loss of consciousness occurred. The course of the disease is very rapid, termination by death or by cure. In most of the patients who died in 24 hours or a little after, the body is covered with purple spots at the moment of death or very little time afterward.*[217]

Today, *Neisseria meningitidis* continues to be a cause of endemic and epidemic disease. In the United States, approximately 800 to 1500 cases of invasive disease occur each year and 95 to 97 percent of these cases are sporadic.[40,45] However, epidemics in developed and developing countries are still occurring and serve as a reminder of the potential virulence of this organism.

The reader is referred to the excellent reviews of meningococcal disease that have been published recently.[52,101]

MICROBIOLOGY

The *Neisseria* genus was named for Dr. Albert Neisser, who described the organism of gonorrhea in 1879. The genus *Neisseria* contains two species important in human disease, *N. gonorrhoeae* and *N. meningitidis*. In addition, several species are part of the normal flora of humans and animals. *N. sicca*, *N. lactamica*, *N. subflava*, *N. flavescens*, *N. mucosa*, *N. cinerea*, *N. polysaccharea*, and *N. elongata* are human commensals; they only occasionally cause human disease.[137]

N. meningitidis is a gram-negative coccus, usually less than 1 μm in diameter. It classically occurs in pairs, with adjacent sides flattened, resembling kidney beans. Occasionally, the organism divides in two planes at right angles to one another, which results in the formation of tetrads. The organisms are nonmotile, are aerobic (but facultatively anaerobic), produce catalase and oxidase, and may be encapsulated. *N. meningitidis* oxidizes glucose and maltose to acid. This distinguishes it from *N. gonorrhoeae*, which oxidizes only glucose. However, certain rare strains of *N. meningitidis* have been reported that fail to produce acid from either glucose or maltose. Fresh isolates have complex nutritional requirements, growing best on chocolate or blood agar. Incubation in a humidified 10 percent carbon dioxide environment is not essential, but enhances growth. Morphologically, the colonies are bluish-gray in appearance and will produce β-hemolysis after 48 to 72 hours of incubation on 5 percent horse blood agar.[28]

N. meningitidis can be transformed by DNA originating in other *Neisseria* spp. Thus, when a *Neisseria* spp. cohabiting the nasopharynx with *N. meningitidis* dies and releases its DNA, the coresident meningococcus can take up the DNA and incorporate it into its genome. Although this sequence of events is very rare, if the new DNA confers a selective advantage to the recipient meningococcus, the trait encoded by the incoming DNA may be retained in future progeny. This is the mechanism by which sulfonamide resistance and penicillin G resistance have arisen in *N. meningitidis*.[137] Many commensal *Neisseria* spp., which also inhabit the nasopharynx, are relatively resistant to penicillin G. DNA fragments from these commensal strains, encoding penicillin resistance, can be detected in penicillin-resistant *N. meningitidis*.[188] Transformation of new DNA into *N. meningitidis* also can introduce genes that modify the structure of the bacterium. Serotyping of groups A, B, and C meningococci has provided valuable macroepidemiologic information.[82] It is clear that as a population develops immunity to one capsular polysaccharide, the organism is capable of acquiring DNA encoding for an alternative capsule. Serogroup B to C and C to B switching has been reported.[197,204,218] Horizontal gene transfer appears to occur from commensal *Neisseria* to *N. meningitidis* of genes whose products aid the bacterium in surviving in the host, or are involved in housekeeping functions.[135] This phenomenon is probably responsible for the occasional report of commensal *Neisseria* causing meningitis.[10]

In addition to the transformation route for varying the antigenic phenotype, meningococci also may exhibit phase variation, which allows for variance of the number of surface antigens. It has been estimated that there are at least 65 genes in *N. meningitidis* subject to phase variation including *por*A.[77,211] Capsule synthesis may be switched on and off by this mechanism.

Like other gram-negative bacteria, *Neisseria's* outer and inner cell membranes are phospholipid bilayers. These membranes sandwich a layer of peptidoglycan. Lipo-oligosaccharide, which is similar to the lipopolysaccharide seen in gram-negative enteric bacteria, is associated with the outer leaflet of the outer cell membrane. Outer membrane proteins that function as porins are an integral part of the outer membrane. Some of these outer membrane proteins are opacity proteins and facilitate adherence and invasion.[151] Outside the outer membrane meningococci possess a polysaccharide capsule that protects the organism from phagocytosis.

Meningococci also have pili, which seem to be important in some phases of adherence to host cells, colonization, and invasion. The genes that code for pili can be turned on and off, so that the organism at times may not express pili. A recent study reported that posttranslational modification of the type IV pili by phosphoglycerol altered the pilin structure and destabilized the pili bundles, resulting in reduced bacterial aggregation on the mucosal surface, which allowed the organism to better cross epithelial monolayers to produce systemic invasion.[47] Antigenic variation of pili by a cassette mechanism allows the bacterium to escape the host's immune system.[93] In addition, both outer membrane proteins and lipo-oligopolysaccharide display antigenic variation by phase variation.

For epidemiologic purposes, meningococci are divided into serogroups, serotypes, and subtypes. Differences in capsular polysaccharides, outer membrane proteins, and lipo-oligosaccharides constitute the basis for these classifications. The capsular polysaccharides are antigenic and the basis for serogroup designation. Thirteen serogroups currently are recognized: A, B, C, D, H, I, K, L, X, Y, Z, W-135, and 29E.[226] Serogroups A, B, C, W-135, X, and Y are the most common causes of invasive disease worldwide.

Serotyping of organisms is based on antigenic differences in outer membrane proteins termed *porins*. Porins are protein channels in the outer membrane that permit nutrients and certain antibiotics to diffuse into the periplasmic space. A single locus encodes porin B, but two mutually exclusive alleles have antigenic differences. All meningococci have either antigenic class 2 or class 3 porin B. These differences permit serotyping. Subtypes are differentiated based on antigenic differences in porin

A. This highly variable antigen is called a class 1 outer membrane protein. Multiple serotypes and subtypes have been identified. Antigenic specificity is achieved by the generation of monoclonal antibodies to the major protein (primarily class 2 or 3), lipo-oligosaccharide, and class 1 protein. The designation B:2a:P1.1:L3,7 indicates that the serogroup B strain is an "a" subtype of class 2 proteins, is a "1" of class 1 protein, and possesses two lipo-oligosaccharide antigens: 3 and 7.[89]

Type 2 protein antigen is isolated from more than 50 percent of cases in the United States and Canada and is an antigenic determinant in serogroup B and C strains. These protein antigens not only are important as epidemiologic markers but also can induce protective bactericidal antibodies.[83]

EPIDEMIOLOGY

Epidemiology in the United States

Invasive infections caused by *N. meningitidis* are reportable through the National Notifiable Surveillance System in the United States. The number of U.S. cases reported to the Centers for Disease Control and Prevention (CDC) in 2008, 2009, 2010, and 2011 were 1172, 980, 845, and 759, respectively.[46] The recent numbers reflect the lowest number of cases ever reported in the United States.[46]

The incidence of meningococcal disease varies significantly by geographic location. Endemic disease, which occurs in developed countries such as the United States and Europe, has an incidence range of 0.15 to 3.0 cases/100,000 population per year.[40,101] The U.S. Active Bacterial Core Surveillance (ABC) system tracks invasive disease caused by encapsulated organisms in selected counties of 10 states geographically dispersed throughout the country. This reporting system covers a U.S. population of 42 million people. In 2010, the overall incidence of invasive meningococcal disease for the United States was estimated to be 0.15/100,000 population.[40] Of cases reported through the ABC system, 46 percent were meningitis, with a fatality rate of 12.8 percent, and 31 percent of cases were bacteremia, with a fatality of 1.1 percent. The rate of invasive disease was 0.27/100,000 population for African Americans and 0.2/100,000 for whites. Of cases in the 2010 ABC Surveillance Report, 20 percent were serogroup B, 30 percent were serogroup C, 48 percent were serogroup Y, and 2 percent were other serogroups. This serogroup analysis excluded Oregon because of an outbreak of serogroup B disease in Oregon at the time.[40]

Serogroups A, B, C, and Y account for more than 90 percent of meningococcal disease worldwide. The incidence of serogroup C and serogroup Y disease has increased in the United States over the last few years, associated with antigenic shifts involving outer membrane protein genes.[102] Disease caused by serogroup W-135 is infrequent, and like disease in serogroup Y has been associated with meningococcal pneumonia.[186,220]

In 2006, Brooks and colleagues[26] reported on an analysis of 69 outbreaks of meningococcal disease that occurred in the United States from 1992 to 2002. Outbreak-associated cases represented less than 2 percent of total cases of invasive disease. Additionally, outbreak-related cases were associated with a higher case fatality rate than sporadic cases (21% vs. 11%; odds ratio 3.3; 95% CI 2.0 to 5.5).[26]

Meningococcal disease, in the United States, peaks during the months November through March.[186] The highest attack rate is seen in February, and the lowest attack rate occurs in September.

The risk for meningococcal disease is related inversely to age, with the highest rates of disease occurring in children younger than 1 year of age.[34] Up to 49 percent of the cases occur in children younger than 2 years of age.[111] However, in epidemics an age shift occurs, with older children, adolescents, and young adults more often affected.[36] A progressive increase in the development of protective antibodies against meningococci occurs between the ages of 2 and 12 years. Neonates usually are protected, if the mother has antimeningococcal antibody, by passive in utero immunoglobulin (Ig)G transfer. In general, the development of bactericidal antibodies to meningococci increases in children at a rate of about 5 percent per year.[89]

International Epidemiology

In developing countries, the incidence rate of invasive meningococcal disease is about 10 to 20 times higher than in the United States (10 to 25/100,000 inhabitants/year).[94] The highest rate of meningococcal disease is in a multicountry belt across sub-Saharan Africa, which has been termed the *meningitis belt*. Serogroup A meningococcal disease is prevalent there and occurs in epidemics during the dry season.[174] During epidemics, the incidence of meningococcal disease is as high as 1000/100,000 inhabitants (1%). Spread of clonal strains of serogroup A meningococcus may be a factor in Africa's unusually high rate of epidemic disease. Clonal strains can migrate transcontinentally and cause epidemics, such as the clonal serogroup A meningococcus, electrophoretic type III-1 (ET III-1) that caused epidemics in China, Nepal, Saudi Arabia, Chad, and Kenya in the 1980s.[145,147,166]

Epidemics occur in the meningitis belt in sub-Saharan Africa each year, affecting thousands of individuals. In 2009, 14 African countries implemented enhanced surveillance during the epidemic season and reported 88,199 suspected cases, including 5352 deaths, the largest number since a 1996 epidemic. Although serogroup A is the predominant serogroup causing epidemic disease in Africa, serogroup X was responsible for more than half of the fatalities from meningococcal meningitis in Burkina Faso in 2010.[173,229] In Africa, epidemic disease occurs during the dry season and decreases once the rainy season starts.[166] Males and females are affected equally.

International outbreaks of *N. meningitidis* infections occurred in 1987 and 2000 and were associated with Muslims making the annual pilgrimage to Mecca. The disease spread to persons of all nationalities represented, some of whom returned home before becoming ill.[147,170] In some cases, close contacts of travelers were infected. Several cases in U.S. citizens were attributed to the outbreaks. The 1987 outbreak was linked to serogroup A,

and the 2000 outbreak was due to serogroup W-135.[35,147,170] Saudi Arabia now requires meningococcal vaccine for travelers entering the country to participate in the annual pilgrimage to Mecca.[123]

Colonization and Disease

The epidemiology of meningococcal disease was defined elegantly in a series of observations in New Jersey military recruits. An inverse correlation was noted between the age-related incidence of meningococcal disease in the United States and the prevalence of serum bactericidal activity against three pathogenic strains of *N. meningitidis*.[89,90] Investigators prospectively studied all incoming recruits to Fort Dix and demonstrated that recruits who lacked bactericidal activity to case strains had a 38 percent attack rate if they were exposed and acquired a pathogenic meningococcus strain.[89] Usually, nasopharyngeal carriage was an immunizing process. Carriage induced the formation of protective antibodies against homologous strains but also produced cross-reacting antibodies to heterologous strains of pathogenic meningococci. Antibody production typically was seen within 2 weeks of acquisition of carriage.[89,90]

In addition to nasopharyngeal carriage, other processes may contribute to meningococcal antibody formation. Certain strains of cross-reacting bacteria, such as *Escherichia coli* and *Bacillus*, produce capsular polysaccharides that immunologically are identical to the capsules of meningococci serogroups A, B, and C. This is a potential immunizing source against invasive meningococcal disease in the general population.[89,117,216]

Nasopharyngeal carriage of *N. meningitidis* is lowest in infants and children and highest in adolescents and young adults. One study determined that 2.4 percent of asymptomatic infants and children had a positive nasopharyngeal culture for *N. meningitidis* during a nonepidemic period.[140] A study of 1500 Norwegians found the carriage rate in persons 20 to 24 years of age was 32.7 percent and in individuals beyond 25 years of age was 10 percent.[33] Other investigators have shown that approximately 20 percent of children harbor meningococcal species in their nasopharynx, but the majority of these isolates are atypical, nontypable strains, which ferment lactose in addition to glucose and maltose.[89,90]

Nasopharyngeal meningococcal carriage in household contacts of persons with documented meningococcal disease is about 10 percent.[142,158,179] Several studies demonstrated that the carriage rate increases if infants or children are in the home.[118,158] In one outbreak of serogroup C meningococcal disease, the carriage rates were 37.8 percent in households with a case in an infant, 17.5 percent in households with a case in a child, and 6.9 percent in households with disease in an adult.[117]

Nasopharyngeal carriage is common after household contact with an index case, and colonization can persist for weeks to months. Without chemoprophylaxis, up to 35 percent of contacts become colonized by the eighth week. The median duration of carriage is 9 months.[140] However, in nearly 40 percent of individuals, it may exceed 16 months.[92] An association between smoking and increased rate of meningococcal carriage has been demonstrated.[196,202] In addition, passive smoke has been implicated in increasing the risk for meningococcal disease in children younger than 5 years of age by 7.5 times that of the general population.

The factors responsible for converting nasopharyngeal colonization to invasive disease have not been firmly established. Many people who subsequently develop invasive disease are colonized shortly before the illness begins. Likely, these individuals lack bactericidal antibody and for some reason do not develop protective antibody after acquisition of the pathogenic strain. Other risk factors associated with invasive disease include young age, crowding (e.g., new military recruits and college freshmen in dormitories),[5,27,37] lower socioeconomic class,[185] concurrent upper respiratory tract infections,[146,231] intimate kissing with multiple partners,[208] specific immune deficiencies (i.e., properdin or terminal complement),[78] functional or anatomic asplenia,[81] and active or passive smoking.[80,196]

Speculation as to the role of other upper respiratory tract pathogens in meningococcal disease prompted several observations. It was noted that the peak incidence of meningococcal infection mirrors the peaks of such agents as influenza and *Mycoplasma*. Several studies have shown an association between colonization or infection with respiratory tract viruses or *Mycoplasma* and the increased risk for development of meningococcal disease.[32,108,146,191] Simultaneous outbreaks of meningococcal and influenza or echovirus infections have been documented.[107,133,231] In addition, one study suggested that the incidence of meningococcal disease and the resultant morbidity and mortality increased in the 5 weeks after influenza-like syndromes.[146] It has been postulated that viral pathogens may temporarily affect the immune response and facilitate meningococcal disease. It is also possible that disruption of the normal respiratory epithelium occurs with viral infection, and this increases the likelihood that colonizing meningococci might become invasive.[146] Preceding viral respiratory tract disease is not a prerequisite for the establishment of meningococcal carriage or disease. However, its occurrence may increase the risk for invasive meningococcal disease.

A variety of host genetic factors also may influence susceptibility to invasive meningococcal disease. Individuals with late complement component deficiencies (C5, C6, C7, C8, or C9) and properdin pathway deficiencies are at increased risk for meningococcal disease.[78] This usually is an inherited defect, and a history of other members of the family with meningococcal disease or repeated meningococcal infections may exist. Complement factor H is a complement-related protein, and certain polymorphisms in the complement factor H gene have been associated with an increased susceptibility to meningococcal disease.[60,99] Acquired complement deficiencies associated with diseases such as systemic lupus erythematosus, nephrotic syndrome, and chronic liver disease also are associated with increased risk for meningococcal disease.[129] A Russian study found the incidence of complement deficiency in first episodes of meningococcal disease to be about 1 percent.[168] In Italy, the prevalence of complement deficiency in patients with meningococcal meningitis was 17 percent.[57] The decision

of whom to screen for complement deficiency should be made partly based on the prevalence of meningococcal disease in a given country. In countries where the incidence of meningococcal disease is high, complement deficiency is less likely to be found. In countries such as the United States, where the incidence is relatively low, complement screening should be considered because it has implications for family members who can be tested and then immunized and educated regarding their increased risk for meningococcal disease.

The chance of finding a complement or alternative pathway (properdin) deficiency substantially increases in patients with recurrent meningococcal disease or with uncommon serogroups. The prevalence of complement or properdin deficiency in a patient with infection by an unusual serogroup was found to range from 31 to 50 percent.[79,154] Therefore, screening all individuals with unusual serogroups is reasonable. CH_{50} is a generally available test and will screen for combined activity of C1 to C9. If complement deficiency is found, the individual should receive the meningococcal vaccine. In addition, family members should be screened for complement deficiency and all family members should be educated about the disease and immunized with quadrivalent polysaccharide or protein conjugate meningococcal vaccine. Most experts believe that the conjugate vaccine is preferred in the age groups for which the vaccine is licensed (9 months to 55 years).

Some investigators demonstrated that although persons with complement deficiency are more at risk for meningococcal disease, the disease they get often is mild. Meningococcal infection activates the complement system, and lipo-oligosaccharides present in the bacterium's outer membrane probably are responsible for the activation. In fatal cases, intense activation has continued until the time of death.[23] The case-fatality rate in complement-deficient individuals is about 3 percent.[187] It is thought that complement-deficient individuals are unable to maintain the high level complement pathway activation and therefore have less severe disease.

Properdin deficiency, which impairs activation of the alternative complement pathway, is X-linked and has been associated with fulminant meningococcal disease.[64,79] The case-fatality rate in one kindred was 75 percent for persons with meningococcal disease.[18] Screening of individuals with exceptionally fulminant disease or individuals who have a family history of meningococcal infections should be considered. AP_{50} will screen for properdin deficiency in the alternative complement pathway. If a deficiency is documented, those individuals and their family members should receive the quadrivalent meningococcal vaccine to prevent disease from serogroups of meningococcus in the vaccine (conjugate vaccine is preferred in the age groups for which the vaccine is licensed—9 months to 55 years).

Mannose binding lectin (MBL) is a pattern recognition receptor and a component of the innate immune system. Patients with meningococcal disease during childhood have a significantly increased incidence of structural mutations in the genes coding for MBL, leading to deficient MBL function in contrast to that in healthy age-matched controls.[75] Similarly, mutations in genes coding for Toll-like receptor (TLR)4 may also increase susceptibility to meningococcal disease. Human TLR4 mutations are associated with susceptibility to invasive meningococcal disease in infancy.[74]

PATHOLOGY AND PATHOGENESIS

The mechanisms by which meningococci invade humans are only partially understood. We do know that encapsulated, typable meningococci are virulent, whereas nonencapsulated strains are relatively nonpathogenic. Even among encapsulated strains, differences in virulence between case and carrier strains of *N. meningitidis* have been demonstrated in an animal model.[106] The presence of a polysaccharide capsule enhances invasiveness by resisting opsonization and subsequent phagocytosis.

The human nasopharynx is the only natural reservoir of *N. meningitidis*.[199] Once pathogenic meningococci have colonized the respiratory tract of susceptible persons, either the organisms become invasive or the individual develops antibody to the organism, conferring immunity. Meningococci adhere to nonciliated, columnar epithelial cells in the nasopharynx via pili. Binding induces endocytosis of the organism into the epithelial cell, and the bacteria may penetrate the epithelial barrier via phagocytotic vacuoles.[198] If antibody is insufficient and invasion occurs, the individual may become bacteremic. Occasionally, unsuspected meningococcal bacteremia has been detected on blood culture and spontaneously cleared on a follow-up culture without antibiotics.[202] However, in most cases, this does not occur and the individual becomes progressively sicker. Bacteria in the blood may seed the meninges and cause meningitis.

Meningococci are gram-negative organisms, and lipo-oligosaccharide is a major component of the bacterial cell membrane. Meningococci release blebs from their surfaces that contain an outer membrane laden with lipo-oligosaccharide. Lipo-oligosaccharide is a potent endotoxin and concentrations of it correlate with severity of disease.[23-25] Lipo-oligosaccharide induces release of a host of inflammatory and anti-inflammatory mediators whose concentrations are also correlated with severity of disease: tumor necrosis factor (TNF)-α, γ-interferon, interleukin (IL)-1, IL-6, IL-8, IL-10, and IL-1 receptor antagonist.[87,130,212,213,222] TNF-α downregulates thrombomodulin expression on endothelial cells, leading to decreased activity of proteins S and C.[53,152] Like TNF-α, many of the mediators directly or indirectly contribute to the formation of a procoagulant state, which results in the formation of microthrombi characteristically found in the skin, digits and extremities, and organs.

Cytokines play an important role in the development of shock frequently seen in meningococcemia. Cytokine release causes neutrophil activation and upregulation of adhesion molecules that may promote endothelial damage and capillary leak.[72] Vasodilation also may occur secondary to increased production of nitric oxide by the endothelial cells.[144] Compensatory vasoconstriction of splanchnic, skin, and renal vessels may subsequently not be enough to maintain adequate blood pressure. Endotoxin-related or cytokine-mediated cardiac

dysfunction also may contribute to development of heart failure and hypotension.[161] Profound capillary leak in the pulmonary bed may lead to the development of acute respiratory distress syndrome (ARDS).

The disseminated intravascular coagulation commonly seen in meningococcemia is believed to be a consequence of activation of the coagulation system by endotoxin.[182] Experimental animal work suggests a synergistic effect of meningococcal endotoxin and materials egested from leukocytes containing meningococci in the initiation of disseminated intravascular coagulation.[66]

The pathologic purpuric lesions seen in fulminant meningococcal disease are similar to those that the generalized Shwartzman reaction induces in rabbits by endotoxin. Pathologically, these lesions show evidence of microthrombi in the small dermal vessels, endothelial damage, and hemorrhage. Inflammatory vasculitis is mediated by upregulation of endothelial adhesion molecules, neutrophil activation, and effects of cytokines and bacterial endotoxin.[7,58,105] Circulating concentrations of endotoxin in patients with meningococcemia may be 50 to 100 times that of other gram-negative infections.[169] In addition, meningococcal endotoxin is more potent than endotoxin from enteric bacilli.[61]

A pathologic study of 200 fatal meningococcal infections illustrates the ability of the meningococcus to affect virtually any organ, either directly or indirectly.[100] Approximately 40 percent of the patients had both meningococcemia and meningitis. Except for adults with meningitis, the average survival time for all cases was 72 hours or less. The major organ systems involved at autopsy in these 200 cases were heart, central nervous system, skin, mucous and serous membranes, and adrenals. Myocarditis occurred in 78 percent of cases. Cutaneous hemorrhages occurred in 69 percent of the fatal infections and ranged from isolated petechiae to diffuse purpura. Acute meningitis was noted at autopsy in 68 percent, with brain abscesses noted in two patients. In almost half the cases with acute meningococcemia, *N. meningitidis* was isolated from otherwise normal cerebrospinal fluid (CSF). Adrenal hemorrhage and necrosis were found in 48 percent of autopsy cases. Diffuse adrenal hemorrhage occurred in approximately 50 percent of adult cases and in more than 80 percent of pediatric cases. Focal areas of inflammation and petechial hemorrhage were seen in many other tissues, including the synovium, skeletal muscle, and the tracheobronchial tree. An association was seen between the pathologic findings and the infecting serogroup of *N. meningitidis*. Serogroup A infections most frequently were associated with encephalitis; serogroups B and C infections were associated with necrotizing myocarditis.

CLINICAL MANIFESTATIONS AND DIFFERENTIAL DIAGNOSIS

The spectrum of disease caused by *N. meningitidis* ranges from asymptomatic transient bacteremia, which clears spontaneously, to fulminant sepsis resulting in death only a few hours after the first symptoms occur.[202] In 2006, Kaplan and colleagues (the U.S. Multicenter Meningococcal Surveillance Study Group)[116] reviewed 159 episodes of invasive meningococcal disease seen at 10 children's hospitals in the United States between January 2001 and March 2005. Meningitis was the most common manifestation of disease seen in 70 percent of cases. Of the children with meningitis, 27 percent had bacteremia alone and 4.4 percent had fulminant disease. Fifty-five percent of children had petechiae, and 38 percent had purpura. Hypotension was present in 10 percent and thrombocytopenia in 6 percent on admission. The overall mortality rate was 8 percent and was significantly greater in children older than 10 years than in children younger than 11 years ($p < .01$). Hearing loss occurred in 12.5 percent of children with meningitis. Skin necrosis occurred in 9.4 percent of children, and 2.4 percent required skin grafts. One percent of children underwent amputations; one child lost all 4 limbs. Only one penicillin intermediate isolate was identified in this study, and no penicillin-resistant isolates were found.

Meningococcemia and Meningitis

Serious or invasive disease usually presents in one of two ways: meningococcemia or meningitis (either with or without meningococcemia). It is important to consider other etiologies in the differential diagnosis of meningococcemia (Table 88-1).

The signs and symptoms of meningococcemia are variable. Early on, evidence of an upper respiratory tract infection may be seen, including coryza, pharyngitis, tonsillitis, and laryngitis. Patients generally are febrile, with complaints of headache, lethargy, and vomiting. Severe myalgias with muscle tenderness and joint pain also may be the presenting symptom.[109] The typical patient with meningococcemia has a short history of upper respiratory tract symptoms, fever, and a hemorrhagic rash. The patient often develops signs of severe circulatory collapse.

TABLE 88-1 **Differential Diagnosis Meningococcemia**

Infectious
Rocky Mountain spotted fever
Ehrlichia
Streptococcal pneumoniae sepsis
Haemophilus influenzae type B sepsis
Group A *Streptococcus* sepsis
Other bacterial sepsis with disseminated intravascular coagulation (i.e., enteric gram-negative organisms)
Infective endocarditis
Gonococcemia
Rat bite fever
Typhus
Secondary syphilis
Noninfectious
Henoch-Schönlein purpura
Idiopathic thrombocytopenic purpura
Collagen vascular disease
Neoplastic processes

FIGURE 88-1 ■ Petechial lesions are seen on the face and neck of a young child with meningococcemia.

FIGURE 88-2 ■ Extensive purpuric lesions occurring in a child with overwhelming meningococcemia and disseminated intravascular coagulation.

It is not unusual for purpura and shock to develop within hours of the first onset of symptoms.

The skin manifestations of meningococcemia range from diffuse mottling to extensive purpuric lesions (Figs. 88-1 and 88-2). Unfortunately, some variation exists in the type of rash seen. Petechiae or purpura are present in 50 to 60 percent of patients.[118,228] Maculopapular rash alone is reported in 10 to 13 percent of patients.[141,228] In children, 20 to 30 percent may have no rash at presentation.[228] This makes differentiation from a viral exanthem particularly difficult. A pink macular rash resembling early varicella is another variant sometimes seen in children with meningococcemia; these lesions often are tender. They may occur in crops, as do the petechiae, and are seen most frequently on the trunk and extremities.[68,104]

The finding of petechiae or purpura in a febrile child should increase the index of suspicion for meningococcemia or other serious disease (e.g., infectious, neoplastic, immunologic). Acral distribution of a rash particularly is worrisome for meningococcemia or another infectious vasculitic process. In two studies, involving more than 200 patients with fever and petechiae (not purpura), 8.0 to 20.2 percent had invasive bacterial disease.[215,228] Seven to ten percent of the total group had infections caused by *N. meningitidis*. Therefore, it seems reasonable to obtain blood cultures on most febrile patients with petechiae. Lumbar puncture should be performed if clinically indicated or if the blood culture ultimately is positive. Antibiotic therapy should include coverage for meningococcus.

Purpura is noted in 16 to 24 percent of patients.[171,228] When purpura is extensive and accompanied by shock it is referred to as *purpura fulminans*. Acquired protein S and C deficiencies have been described in some patients with purpura fulminans.[171,172] One study showed a mortality rate of 50 percent in patients who developed purpura. Progressive purpura was accompanied by declining protein C levels, and the level of protein C was related inversely to the clinical severity of the disease.[171]

Patients with meningitis often are febrile, with headache, vomiting, irritability, stiff neck, and sometimes seizures. A history of lethargy may be present, or the patient may be obtunded. In neonates, physical findings of meningismus, such as Kernig and Brudzinski signs, often are absent. The anterior fontanelle, if open, may be full and tense.

The most common neurologic complications of meningitis are hydrocephalus, cranial nerve palsies (especially hearing loss), subdural effusions or empyemas, cerebral edema, cortical vein thrombosis, and cerebral infarctions. Neurologic sequelae are much more common in patients with meningitis, but complications such as cerebral infarction also can be seen in children with meningococcemia and shock.[158]

Cerebral edema and cranial nerve palsies may be seen at presentation or develop shortly thereafter. Sixth nerve or third nerve palsies are suggestive of increased intracranial pressure and impending herniation, respectively. The development of either of these signs indicates an urgent intracranial process. Hearing loss occurs in 5 to 10 percent of patients with meningitis. Auditory testing should be performed on all patients with meningitis after recovery.

Subdural effusions or empyemas should be considered in patients with fever persisting after 8 days of therapy, vomiting, or development of signs of increased intracranial pressure after the initial few days of treatment. Drainage is recommended only if the effusions are infected (empyemas) or are large enough to produce either focal neurologic signs or increased intracranial pressure.[159]

Vascular thrombosis and cerebral infarction can be due to arterial or venous thrombosis. Venous thrombosis is more common and generally is not seen before the second week. Hemorrhagic infarction of the brain may occur then. Cerebral infarction also may be seen in patients without arterial or venous thrombosis who are in shock with prolonged hypotension and cerebral ischemia. Cerebral infarction in these individuals is an early event.

Hydrocephalus occurs most frequently in young children and those with delayed diagnosis or severe disease. It tends to present 3 to 4 weeks after the onset of illness. Inflammation, with collagen deposition and proliferation of fibroblasts in the meninges, produces an obstruction to the flow of CSF. Progressive increase in head circumference should alert the clinician to the possibility of hydrocephalus.[159] Imaging (i.e., computed tomography and magnetic resonance imaging) studies are diagnostic.

Neonatal meningococcemia and meningitis are uncommon but have been reported. In one report, a 2-week-old infant died after a brief febrile illness with both CSF and blood cultures positive for meningococcus. Maternal endocervical colonization was documented. In addition, the mother's pharyngeal culture grew *N. meningitidis*.[114] If endocervical colonization by *N. meningitidis* is found prenatally, treatment with antibiotics should be considered in an attempt to eradicate colonization before delivery or intrapartum antibiotics should be given. Ceftriaxone would seem to be a reasonable choice. Rifampin and ciprofloxacin are not advocated for use during pregnancy.

Chronic Meningococcemia

Chronic meningococcemia, first described in 1902, is defined as meningococcal septicemia without meningeal symptoms in which fever has persisted for at least a week before any antibiotic therapy.[70,157] Benoit[13] reviewed 148 cases of chronic meningococcemia in the United States in 1963 in patients ranging in age from 3 months to 62 years. The major symptoms included fever and chills (present in 100 percent of patients), skin rash (93.2%), arthralgias (70.3%), and headache (61.5%). The patients generally were not in a toxic state and were in good health before becoming infected. The mean duration of illness before diagnosis was 6 to 8 weeks (range, 1 to 40 weeks). Symptoms tended to be intermittent; the rash often appeared in association with fever and then disappeared over the next several days. Bacteremia also was intermittent in some patients. In the Benoit study, in the average patient, five blood cultures were obtained before meningococci were isolated. However, after a blood culture yielded the organism, most subsequent cultures were positive. In children, some investigators report that it is common to isolate the organism in the first blood culture.[131] The arthralgias also tended to be intermittent in nature.

In Benoit's series,[13] almost 40 percent of the patients with chronic meningococcemia developed localizing complications. The meninges were the most common site of localization; meningitis developed in 15.5 percent of patients. Other localized infection included carditis, nephritis, epididymitis, conjunctivitis, iritis, and retinitis. In only one instance was an organism recovered from the joint. The average duration of meningococcemia in those patients with complications was 10.2 weeks, in contrast to 4 to 8 weeks in patients without any localization.

The diagnosis is established by identifying the organism in blood cultures. Antibiotic therapy results in prompt defervescence and dramatic recovery.

The pathophysiologic mechanisms permitting chronic meningococcemia remain unclear. No evidence suggests that the organisms are less virulent than other meningococci; thus, a defect in host immunity has been suggested. A hypersensitivity basis for this disease has been postulated, and it is theorized that the skin changes and arthritis may be secondary to antigen-antibody complexes.[158] In contrast to acute meningococcemia, bacteria are almost never found by biopsy or culture of skin lesions. The histologic findings of the skin lesion are distinct from those seen in skin lesions of patients with acute meningococcemia.[13,100,158]

Meningococcal Pneumonia

Meningococcal pneumonia occurs in conjunction with meningococcemia or meningitis in 8 to 15 percent of cases.[122] However, the meningococcus also can play a role as a primary respiratory pathogen.

Primary meningococcal pneumonia, once considered a rare disease, now is recognized as the most common form of meningococcal disease in certain military recruit populations and has been reported to cause 4.5 percent of all bacterial pneumonias in a general hospital population.[122,134]

Patients with preceding viral pneumonias are at risk for meningococcal pneumonia; more than 100 cases of meningococcal pneumonia occurred during the influenza pandemic of 1918 and 1919. In addition to disease among military recruits, nosocomial acquisition of meningococcal pneumonia in hospitalized patients has been reported.[51]

The diagnosis of meningococcal pneumonia is difficult because isolation of the organism from the sputum does not distinguish a meningococcal carrier from an individual with meningococcal pneumonia. In addition, routine sputum cultures do not include media selective for the meningococcus. Blood cultures are positive in only 15 percent.[122]

Koppes and associates[122] reported on 68 cases of meningococcal pneumonia; diagnostic criteria included a compatible clinical syndrome and isolation of *N. meningitidis* from pleural fluid or blood.[122] All 68 meningococcal pneumonia cases were serogroup Y; during the same period, 10 cases of meningococcemia and 6 cases of

meningitis were caused by serogroup Y. The high ratio of pneumonia to meningitis in this study suggests that serogroup Y organisms may be more likely to cause pneumonia than other serogroups, which has been substantiated by other investigators.[175,185] Pneumonia caused by serogroup B or C meningococci has been reported, usually in association with meningococcemia or meningitis.[227]

Primary meningococcal pneumonia usually is associated with a gradual onset of symptoms and a history of an antecedent upper respiratory tract infection. Rales and fever are found in most patients, and 80 percent have pharyngitis. The radiograph often shows involvement of lower lobes with patchy alveolar infiltrates. More than one lobe is involved in 40 percent. Twenty-five percent have pleural effusions. Petechiae, purpura, or shock were not present in any of the patients with pneumonia reported by Koppes and colleagues.[122]

The pathogenesis of this disease is thought to be pulmonary infection via droplet inhalation. The epidemiologic importance of meningococcal pneumonia was emphasized in a report from the Centers for Disease Control and Prevention (CDC) discussing nosocomial transmission of serogroup Y *N. meningitidis* in oncology patients.[51] The index case had meningococcal pneumonia. One other patient in an adjacent room developed meningococcal bacteremia; in three additional patients, serogroup Y *N. meningitidis* was isolated from nasopharyngeal cultures. Airborne dissemination seemed to be the mode of transmission. Respiratory isolation for a patient with suspected meningococcal pneumonia is indicated.

Penicillin therapy of penicillin-sensitive meningococcal pneumonia results in a prompt clinical response. Of the patients reported by Koppes and colleagues,[122] 93 percent were afebrile after 3 days of therapy. Third-generation cephalosporins, such as ceftriaxone and cefotaxime, may be the current drugs of choice pending definitive identification.

Other Meningococcal Syndromes

Conjunctivitis

Primary meningococcal conjunctivitis is indistinguishable clinically from acute bacterial conjunctivitis caused by other organisms. Usually, it presents in children as the acute onset of unilateral purulent conjunctivitis.[11] It has been reported in individuals from 2 days of age to adulthood.[35] Gram stain of the purulent material typically shows gram-negative diplococci that may sometimes be confused with gonococcal conjunctivitis. Barquet and colleagues[12] showed that 44 percent of the isolates were serogroup B meningococci.

The complications of primary meningococcal conjunctivitis reported by Barquet and colleagues[12] included sepsis or meningitis in approximately 18 percent of patients. The symptoms of systemic meningococcal disease occurred 3 to 96 hours after the onset of the conjunctivitis (mean, 41 hours). Patients treated only with topical therapy at the time of conjunctivitis were 19 times more likely to develop systemic disease than were patients treated with systemic therapy ($p = .001$). Ocular complications occurred in 15.5 percent of patients and included corneal ulcers (10.7%), keratitis, hemorrhage, and iritis.

Pharyngitis

The diagnosis of meningococcal pharyngitis is difficult because, like group A β-hemolytic streptococci, the isolation of meningococcus from the pharynx does not establish that this organism is the etiologic agent. In fact, most individuals who harbor meningococci in their nasopharynges are asymptomatic carriers. However, Banks[9] noted overt nasopharyngitis in one third of patients with meningococcal sepsis or meningitis. Pizzi,[167] describing a severe epidemic of meningococcal meningitis, noted that individuals with sore throats often had a pure culture of meningococci.[169] Olcen and associates[158] cultured family members of 21 consecutive cases of meningococcal disease and found that 61 percent of family members with sore throat or other upper respiratory tract symptoms were meningococcal carriers, in contrast to 14 percent of asymptomatic family members.[158]

On occasion, culture samples are obtained in individuals in the community with symptomatic pharyngitis, and the laboratory reports growth of *N. meningitidis*. If the patient is febrile but otherwise appears well, we recommend a blood culture and intramuscular or intravenous ceftriaxone. If the blood culture result is negative, the patient should be treated with an antibiotic that will eradicate the meningococcus (see discussion of chemoprophylaxis). If the patient is afebrile and asymptomatic at the time the culture results are obtained, we recommend eradication of the organism using one of the antibiotics recommended for chemoprophylaxis.

Arthritis

Meningococcal arthritis occurs primarily in adults. The overall incidence, as a complication of bacteremia, is approximately 2 to 14 percent.[95,228] Meningococcal arthritis has two forms. The first is seen within the first few days of treatment and is characterized by severe arthralgias and few objective signs of joint inflammation. It is suggested that the pathogenesis of this arthritis is an inflammatory response to viable organisms that have seeded the synovium during the initial bacteremia. The second, more common, form appears to be an immune complex phenomenon. It usually is noted 3 to 7 days after the recognition of meningococcemia, often at a time when the patient appears to be improving from the meningitis or sepsis. The knee, wrist, elbow, and ankle joints are involved most commonly.[95]

In both forms, the arthritis usually is monoarticular or oligoarticular with an effusion, with minimal pain, erythema, and limitation of motion. It is very unusual to culture organisms from the effusion; joint fluid culture yields meningococci in fewer than 10 percent of cases. The exception to this is a child with suppurative arthritis on initial presentation. In one study, 8 percent of patients

with meningococcal infections had arthritis; 75 percent had positive culture results when cultures were obtained before receiving antibiotics.[227,228]

Synovial fluid leukocyte counts vary widely, but counts greater than 100,000/mm^3 have been reported.[165] The appearance of arthritis often is accompanied by a rise in temperature; in 7/47 patients with arthritis, a characteristic skin lesion appeared at the same time.[93] These lesions began as skin hyperpigmentation but progressed to vesiculation and ulceration; biopsies showed vasculitis. Additional evidence of concurrent vasculitis is suggested by reports of patients developing episcleritis and mild proteinuria simultaneously with arthritis.[93]

On histologic examination, the synovium is infiltrated with mononuclear cells that contain IgM, C3, and meningococcal antigen.[94] This strongly suggests an immune complex–mediated disease. No specific therapy is indicated, and the arthritis resolves spontaneously. Controversy exists regarding the role of intermittent closed drainage of the joint space.[19] Permanent joint deformity is uncommon in this disease, occurring in approximately 10 percent of cases.[190] Edwards and Baker[71] reported allergic complications of meningococcal disease in 10 percent of the 86 children followed prospectively. More than 83 percent were serogroup B, although late-onset arthritis and vasculitis also have been reported with serogroup A and C disease.

Permanent joint damage is unusual, occurring in about 1.5 percent of patients with arthritis. Potential sequelae include ankylosis, decreased range of motion, and bone necrosis.[129]

Pericarditis and Myocarditis

Pericarditis, as a complication of meningococcal disease, occurs in 3 to 5 percent of cases, although one series reported a 19 percent incidence in 32 patients with meningococcal meningitis.[69,148] It generally occurs in patients with meningococcemia but has been reported as an isolated event without septicemia or meningitis.[103]

Pericarditis is presumed to be a late complication of meningococcal disease because clinical symptoms such as fever, dyspnea, or substernal chest pain (or even cardiac tamponade) usually do not appear until the fourth to the seventh day of illness. However, several investigators have noted early evidence of pericarditis based on electrocardiographic or radiographic data of patients examined at the time of hospital admission.

Because most symptomatic pericardial effusions develop late in the course of the illness, are serous, and are sterile, the pathophysiologic mechanism is presumed to be an immune complex reaction. Uncontrolled studies report the successful use of steroids in the treatment of this complication.[104] However, one report documents pericarditis and the development of tamponade in a patient receiving steroids.[162]

The clinical course of meningococcal pericarditis usually is benign, but pericardial compression requiring pericardiocentesis occurs.[164] Early relapses also have been reported, but these were self-limited. The development of constrictive pericarditis requiring pericardectomy has been reported.[162,192,221]

Myocarditis was noted at autopsy in 78 percent of patients with fatal meningococcal disease.[100] Myocarditis was noted most often in adults but was more severe when it occurred in children. Rosenblatt and colleagues[183] noted myocarditis at autopsy in 10/12 children with fatal meningococcal infection. On pathologic examination, these cases showed collections of inflammatory cells in the myocardial interstitium and focal extravasation of erythrocytes with acute vasculitis. Abscesses and endocarditis were not seen. Inflammation occasionally may involve the atrioventricular node and has been reported as a cause of sudden death in a patient recovering from meningococcal meningitis.[181]

Miscellaneous Meningococcal Infections

Several unusual syndromes have been reported, including primary meningococcal pericarditis,[215] mesenteric adenitis,[126] peritonitis,[126] and genitourinary infections.[76]

LABORATORY FINDINGS AND DIAGNOSIS

Wong and colleagues[228] reviewed 100 cases of meningococcal infections in children seen at their institution between 1985 and 1988. Leukopenia (white blood cell count <5000/mm^3) was present in 21 percent, and thrombocytopenia was noted in 14 percent. Fifty-five percent of patients had meningitis. Eleven percent of those with culture-positive meningitis had no CSF abnormalities on chemistries or examination.

Hyponatremia is seen in some patients with meningitis. Inappropriate secretion of antidiuretic hormone is the mechanism. In a study of 43 children with meningococcal meningitis, 7 percent developed syndrome of inappropriate secretion of antidiuretic hormone.[73]

Other laboratory abnormalities seen in patients with sepsis or shock include abnormal coagulation panels (disseminated intravascular coagulation), acidosis, and abnormal liver function studies.

The gold standard for diagnosis is based on recovering the organism from blood, CSF, or petechiae. Blood culture alone is positive about 50 percent of the time in patients who have not received antibiotics.[228] Rapid diagnosis often can be made by Gram stain of the CSF in patients with meningitis. Characteristic gram-negative diplococci are seen. Caution should be exercised in relying solely on the Gram stain to determine the initial antibiotic regimen. Broad-spectrum antibiotic therapy should be initiated pending identification of the organism by culture. Overdecolorized gram-positive cocci of *Streptococcus pneumoniae*, on occasion, have been confused with meningococci on Gram stain.

In patients who have skin lesions, a rapid presumptive diagnosis of meningococcemia often can be made by needle aspiration and Gram stain of a skin lesion. Needle aspiration yields gram-negative diplococci on the Gram-stained specimen in about 50 percent of patients with acute meningococcal infections.[214] Culturing the obtained aspirate increases the yield further. Correlation of the Gram stain with the clinical presentation is important

because disseminated gonococcal infections also may present with skin lesions that yield gram-negative diplococci on Gram stain.

Latex agglutination has been used to detect circulating antigen in serum, CSF, and urine of patients with meningococcal disease.[224] Latex agglutinin tests using serum and urine are not recommended. Cross-reactions with certain *E. coli* K1 (cause of neonatal meningitis) or *Bacillus* strains may occur. Latex agglutinin tests using CSF may be helpful in patients pretreated with antibiotics and with a compatible clinical syndrome.[3] These tests are of particular benefit in cases of partially treated meningococcal meningitis in which culture and Gram stain may be negative.

Polymerase chain reaction (PCR), one of the newer tests for detection of *N. meningitides*, may be very helpful in diagnosis of patients who have partially treated meningococcemia or meningitis. Once antibiotics have been given, the chances that a blood culture result will be positive decrease to less than 5 percent.[31] One study showed the sensitivity and specificity of PCR for *N. meningitidis* to be 91 percent in cerebrospinal fluid specimens. Treatment with antibiotics before the test did not decrease the test's sensitivity or specificity.[153] Use of this test in confirming meningococcal infections in patients pretreated with antibiotics may be valuable in subsequent patient management, follow-up, and prompt institution of chemoprophylaxis to contacts. One report from the United Kingdom describes use of a multiplex PCR assay for the simultaneous detection of *N. meningitidis*, *H. influenzae*, and *S. pneumoniae* from clinical samples of CSF and whole blood. Corless and colleagues[55] found that the sensitivities for detection of the three organisms ranged from 88.4 percent to 91.8 percent, with 100 percent specificity. A 2012 article from China and Australia reported development of a multiplex PCR assay for detection of 12 meningococcal serogroups.[232] Commercially available assays such as this would greatly facilitate etiologic diagnosis in children with sepsis or meningitis. Currently, meningococcal PCR is in use in the United Kingdom but is only available in the United States as a research test. Investigators in the UK have utilized quantitative PCR of CSF in patients with culture-proved meningococcal disease. In their experience, the sensitivity of CSF PCR was 89 percent for detection of *N. meningitidis*. In addition, they noted that patients with serogroup B infection had extremely high quantities of bacteria within the CSF regardless of the peripheral blood bacterial quantitation.[59]

MORTALITY AND PROGNOSIS

The overall mortality of invasive meningococcal disease in the United States is 7 to 19 percent.[116,155,184,200] Various scoring systems have been devised in an attempt to predict prognosis in patients with meningococcal disease. These scoring systems were reviewed in an article by Kirsch and colleagues.[121]

The Glasgow Meningococcal Septicaemia Prognostic Score (GMSPS) is a validated scoring system developed to clinically assess patients and facilitate admission of the most severely ill children to intensive care units.[193,205] This scoring system, which evaluates seven key items (i.e., hypotension, difference in skin-core temperature, coma, acute deterioration, absence of meningismus, progressive purpura, and base deficit) has been used by many to define entry criteria into clinical trials.

In a review of 100 cases of meningococcal disease at the Los Angeles Children's Hospital, five features were identified that were correlated with poor prognosis: shock or seizures on presentation, hypothermia, total white blood cell count less than 5000/mm^3, platelet count less than 100,000/mm^3, and development of purpura fulminans. The overall mortality in this series was 10 percent.[228]

Most prognostic scoring systems and clinical reviews agree that purpura fulminans and shock uniformly are poor prognostic signs. Individuals with only meningitis have a lower case-fatality rate than those with bacteremia or an isolate from another source (2% vs. 12%).[184] Presumably, this is a function of virulence of the organism, ability of the immune system to contain the infection, or both. Case-fatality rates also differ by serogroup and are higher in W-135 disease (21%) than in serogroup C (14%), Y (9%), or B (6%).[184]

Evidence suggests a genetic component exists in host cytokine production that may be associated with severity of disease. Westendorp and associates[223] reported that families with low TNF production or high IL-10 production are at increased risk for fatal outcomes with meningococcal disease. Recently, investigators have been studying variants of proinflammatory host genes (TNF-α, IL-1) to see if polymorphisms in these might be linked to severity of disease. Read and colleagues found that homozygosis of certain alleles at the IL-1 locus increased risk for death in individuals with meningococcal disease, and suggested that IL-1 genotype may be associated with fatal outcomes.[178]

TREATMENT

Therapy for meningococcal disease has evolved over the last century. In the early 1900s, treatment consisted of administration of intravenous and intrathecal horse serum and CSF drainage. Mortality associated with this therapy was 26 percent.[104] The use of sulfonamides lowered the death rate to 5 or 10 percent.[96] With the emergence of sulfa-resistant strains, penicillin was added to the regimen and may still be used for susceptible meningococcal infections. In the late 1980s, reports began to appear of meningococci relatively resistant to penicillin. The mechanism of resistance is reduced binding affinity of penicillin-binding proteins. Relatively resistant strains have been reported in the United States, Canada, Europe, South Africa, Romania, and Croatia.[21,112,163,203,231] Isolates that are absolutely resistant to penicillin (minimum inhibitory concentration >1.0 μg/mL) have been documented from Spain and the United Kingdom.[163,203] These strains had acquired a gonococcal plasmid encoding for the production of a β-lactamase.[203]

In 2009, ciprofloxacin-resistant isolates were identified from four unrelated patients with invasive meningococcal

disease in three U.S. states. Three of the cases were infected with serogroup B meningococcus and one with serogroup Y meningococcus. Genetic studies suggested that the Y strain acquired resistance by a point mutation. However, the B strains may have acquired resistance through horizontal gene transfer from *N. lactamica*, a commensal organism carried in the nasopharynx.[230] Ceftriaxone-nonsusceptible strains have been reported from India.[139] Routine susceptibility testing of meningococcal strains is not generally available, but should be considered in special circumstances in which resistance is clinically or epidemiologically suspected.

Prompt institution of antibiotic therapy in suspected meningococcal infections may be life-saving. Children who present with fever and purpura should be considered to have meningococcemia until proved otherwise, while recognizing that other pathogens may present with fever and purpura. A purpura fulminans–like presentation also has rarely been described caused by *Staphylococcus aureus*,[124] group A *Streptococcus*,[67] group B *Streptococcus*, and overt sepsis with other organisms causing disseminated intravascular coagulation. Antibiotics should be administered as soon as possible. A systematic review of the effectiveness of antibiotics given before admission concluded that "the data are consistent with benefit when a substantial proportion of cases are treated."[97] If possible, blood cultures should be drawn before antibiotic administration, but specimen collection should not delay administration of antibiotics. A lumbar puncture can be performed in stable patients, but the procedure should not delay antibiotic administration. CSF obtained after antibiotic therapy may be sterile, but pleocytosis will be apparent. Patients who are unstable or have significant coagulopathy should have the lumbar puncture deferred. Shortly after administration of bactericidal antibiotics, some patients have marked clinical deterioration, including hypotension and sometimes death. Rapid liberation of endotoxin (and resultant stimulation of cytokine release) from lysing organisms may be the cause of this phenomenon.[142]

The clinical presentation of *N. meningitidis* meningitis may be similar to that of meningitis caused by *S. pneumoniae* or *H. influenzae*. Empirical antibiotic therapy should therefore take into consideration the most likely pathogens. In children older than 1 month of age with meningitis, vancomycin and cefotaxime (or vancomycin and ceftriaxone) is an appropriate regimen until a definitive diagnosis is made. Similarly, empirical therapy for children younger than 1 month of age includes ampicillin and cefotaxime, with consideration given to the addition of vancomycin.[186]

For penicillin-susceptible meningococcemia or meningitis, intravenous penicillin G 250,000 to 300,000 U/kg/day (maximum 12 million U/day) given in divided doses every 4 to 6 hours for 7 days, is effective. Third-generation cephalosporins, ceftriaxone 100 mg/kg/day intravenously in two divided doses or cefotaxime 200 mg/kg/day intravenously in four divided doses also are effective. Cefotaxime or ceftriaxone is recommended for travelers from Spain, Italy, and parts of Africa because of reports of penicillin resistance in these areas.[3]

In confirmed cases of meningococcal disease, comparisons of penicillin G with ceftriaxone have shown ceftriaxone to be as efficacious. Necrotic skin lesions were seen more commonly in the penicillin group, but otherwise complication and mortality rates were equivalent.[209] Meningococcal disease has been treated successfully with ceftriaxone intravenously in both the 80 to 100 mg/kg/day and 100 mg/kg/day in two divided doses regimens.[209] Chloramphenicol is an alternative for penicillin-allergic patients. Currently, routine susceptibility testing of meningococcal isolates is not recommended. However, in selected cases in which the patient is not responding as expected, susceptibility testing may be warranted. With all cases of meningococcal disease, eradicating colonization of the index case is important (see discussion of chemoprophylaxis).

Steroid administration in patients with septic shock and meningococcemia is controversial, but several studies have reported adrenal insufficiency (or partial adrenal insufficiency) in 10.3 to 16.9 percent of severely ill children with meningococcemia.[20,62,63,180] For patients with Waterhouse-Friderichsen syndrome, treatment with steroids is indicated. However, treatment of meningococcal meningitis with steroids has been debated in the literature for years. Steroid proponents point to the *Haemophilus influenzae* type b meningitis and *Streptococcus pneumoniae* studies, in which treatment with steroids decreases hearing loss and may reduce neurologic sequelae. They postulate that steroids, through anti-inflammatory effects, may decrease polymorphonuclear neutrophils, macrophages, and cytokines in the central nervous system and thus decrease central nervous system immune-mediated damage and hearing loss. Steroid opponents say that no conclusive studies show steroids to be of benefit in meningococcal meningitis and that risks include gastrointestinal ulceration, decreased penetration of antibiotics into the central nervous system (because of decreased meningeal inflammation), and steroid psychosis. If steroids are used, it seems prudent to use them early (preferably close to the time the first dose of antibiotic is administered). However, antibiotics should never be withheld waiting for steroids to be given.

Experimental and Adjunctive Therapies

Many adjunctive and experimental therapies have been tried or are being evaluated presently. Antiendotoxin therapies and protein C concentrate infusions are the most recent additions (Table 88-2). Two antiendotoxin therapies have been evaluated in clinical trials: HA-1A and recombinant bactericidal/permeability increasing protein (rBPI). HA-1A, a human monoclonal antibody to endotoxin, was evaluated in a randomized, double-blind, placebo-controlled trial in 269 children with severe meningococcemia. Although the 28-day mortality rate in the treatment group was 18 percent in contrast to 28 percent in the placebo group, this was not statistically significant ($p = .11$).[65] BPI is a naturally occurring protein in neutrophil azurophilic granules. BPI binds to and neutralizes the effects of endotoxin. Administration of rBPI was studied in 393 children with presumed

TABLE 88-2 **Recent Studies of Alternative Therapies for Severe Meningococcemia or Sepsis Syndrome**

Year	Study	First Author	Randomized/ Placebo Controlled	Eligible Patients	Patient Number (n)	Results
1997	Activated protein C	Smith[194]	No/No	3 mo–27 yr, severe meningococcemia with septic shock and purpura fulminans	12	0 deaths, 2 patients with amputations. Favorable results compared with historical mortality rate of 50% in patients with shock, and purpura fulminans, and Glasgow meningococcal septicemic prognostic score expected mortality of >80%.
1999	HA-1A	Derkx[65]	Yes/Yes	3 mo–18 yr, petechiae or purpura, hypotension, toxicity, or end organ dysfunction	269	No statistically significant reduction in 28-day mortality demonstrated. Mortality rate HA-1A 18%, placebo group 28% ($p = .11$).
2000*	rBPI	Levin[132]	Yes/Yes	2 wk–18 yr, petechiae or purpura, and severe disease	393	No statistically significant reduction in mortality (7.4% rBPI, 9.9% placebo). Treatment group had fewer amputations, trend toward improved outcomes.
2001†	Activated protein C	Bernard[14]	Yes/Yes	Severe sepsis (any organism, known or suspected) with organ dysfunction	1690	Significant reduction in mortality (30.8% placebo vs. 24.7% treatment group). Increased risk for bleeding in treatment group.
2005‡	Activated protein C	Nadel[150]	Yes/Yes	Pediatric patients with severe sepsis	477	Study stopped after review by Data Safety and Monitoring Committee. No difference in mortality or time to complete organ failure resolution.

*57 patients died before receiving drug or placebo (after randomization) and were not included in this analysis.
†This study enrolled adults presenting with severe clinical sepsis (meningococcemia not a criteria for entrance).
‡This study enrolled pediatric patients presenting with severe clinical sepsis of all types.

meningococcal disease. There was no difference in mortality rates (7.4% rBPI vs. 9.9% placebo). There was a trend in reduction of amputations in the treatment group that approached statistical significance ($p = .067$).[132]

Recombinant protein C concentrate infusions have been studied in adults in a large randomized, placebo-controlled trial of 1690 patients with severe sepsis. A reduction in mortality was demonstrated, but the treatment group had an increased risk for bleeding.[17] Smith and associates[194] compared 12 children with severe meningococcemia and purpura fulminans treated with protein C concentrate to historical controls. No deaths occurred in the treated patients, in contrast to 50 percent in historical controls. A large study, published in 2007, compared activated protein C to placebo in children with presumed meningococcal infection. The study was terminated by the Data and Safety Monitoring Board because of a low likelihood of improved outcome in the treatment group.

Additional supportive measures such as prophylactic low-dose heparin are used by some clinicians.[225] Many investigators have studied the effect of heparin on survival and disseminated intravascular coagulation in patients with meningococcemia, and no consistent beneficial effect on these parameters has been noted. Serious side effects directly attributed to heparin therapy have been reported rarely.[85] The difficulty in adjusting the dose in small infants may lead to heparin intoxication. A retrospective chart review of 24 patients with purpura fulminans showed less necrosis of the digits and extremities in patients treated with heparin, but the results were not statistically significant.[127]

Other experimental therapies have been attempted in patients with fulminant meningococcemia. Anecdotal reports or small case series describe use of tissue plasminogen activator,[2,149] antithrombin III infusion,[50] topical nitroglycerin,[110,143] plasmapheresis,[48] and extracorporeal membrane oxygenation (ECMO).[128] Continuous caudal

block has been used to restore lower extremity perfusion.[206] Insufficient evidence exists to say that any of these therapies have a significant impact on outcomes in meningococcal disease. Larger, multicenter studies are needed to evaluate efficacy.

CHEMOPROPHYLAXIS

The ability of *N. meningitidis* to spread from person to person and cause epidemic disease has been recognized since the 1800s. For this reason, droplet precautions should be continued for 24 hours after initiation of appropriate antibiotics in the hospitalized patient. The secondary attack rate in households with an index case is approximately 1000 times the attack rate in the general population.[4,196] Household crowding and young age are factors that increase the secondary attack rate. The mode of transmission is direct contact with respiratory droplets or secretions. For these reasons, chemoprophylaxis is recommended for household contacts of an index case and for young daycare center contacts. Persons who have had significant contact with the oral secretions of an index case also should be considered for prophylaxis. Several epidemiologic studies suggest that casual acquaintances (e.g., school-aged classmates) are not at increased risk, although some authors report secondary cases in this population.[113,115] Prophylaxis is indicated for health care workers who have had intimate exposure to nasopharyngeal secretions (e.g., mouth-to-mouth resuscitation and endotracheal intubation in the absence of droplet precautions).[86] The period of communicability of the index patient is not well established. Most public health authorities recommend that persons in contact with the patient up to 7 days before onset of illness be considered for prophylaxis. Prophylaxis should be instituted as soon as possible after identification of the index case. It is not necessary to wait for laboratory confirmation of a case if the clinical picture is most consistent with meningococcal infection. Nasopharyngeal cultures are not recommended, because many nonpathogenic *Neisseria* spp. may colonize the nasopharynx.

The index patient should receive chemoprophylaxis before discharge unless he or she has been treated with ceftriaxone (or cefotaxime). Abramson and Spika[1] reported that 4/14 (29%) of patients with meningococcal infection treated with intravenous penicillin had positive culture results from the respiratory tract 1 week after completion of therapy.

Secondary cases originally were defined as occurring more than 24 but less than 31 days after onset in the index case. Using this definition, approximately 50 percent of secondary cases will occur in the first 7 days after presentation of the index case. It is essential to initiate prophylaxis as soon as possible, based on clinical presentation of the index case (e.g., fulminant meningococcemia) or on laboratory culture data if the disease presents as bacterial meningitis, septic arthritis, and so forth.

The original drug used for chemoprophylaxis was sulfadiazine. However, a large percentage of strains now are resistant to sulfa. Table 88-3 lists four antibiotics that are highly effective in eradicating meningococcus from the nasopharynx. Rifampin is generally the drug of choice for chemoprophylaxis of children. It is generally well tolerated but has side effects, including orange urine and sweat, orange staining of contact lenses, and stimulation of liver microsomal enzymes leading to reduction in levels of other concurrent medications (e.g., oral contraceptives, anticoagulants, digoxin, and phenytoin). Development of resistant strains has been reported rarely.[54] Ciprofloxacin, ceftriaxone, and rifampin have been evaluated in a randomized, comparative study.[56] All three drugs were highly effective in carriage eradication. Ceftriaxone probably is the drug of choice for a pregnant contact and also may be indicated for children because a single intramuscular injection may result in greater compliance than four doses of rifampin. A single oral dose of ciprofloxacin is highly effective in eradicating carriage of meningococcus, but it is contraindicated in individuals younger than 18 years because of evidence of cartilage damage in juvenile beagles. In addition, a 2009 article reported four cases of invasive meningococcal disease in the United States with isolates resistant to ciprofloxacin.[230] Azithromycin was studied in a randomized, controlled trial comparing 500 mg of azithromycin orally once to rifampin 600 mg orally twice daily for 2 days. Carriage was eradicated in 56/60 (93%) colonized adults treated with azithromycin in contrast to eradication in 95 percent of the 59 colonized adults treated with rifampin.[88]

TABLE 88-3 **Chemoprophylaxis Regimens for Eradication of *Neisseria Meningitidis***

Drug	Age	Dose/Duration
Rifampin*	Children <1 mo	5 mg/kg/dose PO twice daily for 2 days (four doses)
	Children ≥1 mo	10 mg/kg/dose (maximum dose 600 mg) PO twice daily for 2 days (four doses)
	Adults	600 mg dose PO twice daily for 2 days (four doses)
Ceftriaxone	Children <15 yr	125 mg IM, single dose
	Children ≥15 yr	250 mg IM, single dose
	Adults	250 mg IM, single dose
Ciprofloxacin†	Children	Not recommended
	Adults	500 mg PO, single dose
Azithromycin‡	Children	10 mg/kg PO (maximum dose 500 mg), single dose
	Adults	500 mg PO, single dose

*Rifampin is not recommended for pregnant women (teratogenicity in laboratory animals). The reliability of oral contraceptives may be affected by rifampin therapy; therefore alternative contraceptive measures should be used during and for the month after rifampin administration.
†Ciprofloxacin is not recommended in children, pregnant women, or lactating women. Ciprofloxacin can be used in children if there is no acceptable alternative.
‡Azithromycin is not routinely recommended and is not listed in the CDC recommendations for prophylaxis.
IM, Intramuscularly; *PO,* orally.

As mentioned in the section on meningococcal vaccines, secondary disease also can be prevented by immunization of contacts. We recommend both immunization and chemoprophylaxis whenever possible (realizing that no protection against group B meningococci currently is provided by immunization).

The single most important element of chemoprophylaxis is education of contacts regarding the need for immediate medical attention if they develop signs or symptoms of a febrile illness. No prophylactic strategy is 100 percent effective, and ill contacts should be medically evaluated with a high suspicion for meningococcal disease.

MENINGOCOCCAL VACCINES

Primary prevention of meningococcal disease is essential for several reasons. The presentation may be fulminant, with no opportunity for antibiotics to influence the course of the disease. Antibiotic-resistant strains now are recognized, and chemoprophylaxis of contacts is a cumbersome and often ineffective public health measure. Mass immunization offers the opportunity to prevent both endemic and epidemic disease worldwide.

Two types of vaccines, meningococcal polysaccharide vaccine (MSPV4) and meningococcal conjugate vaccine (MCV), are currently licensed in many countries around the world for prevention of meningococcal disease. Although more costly, meningococcal conjugate vaccines are superior to polysaccharide vaccines in several ways. Children younger than 2 years of age do not produce high levels of antibody in response to pure polysaccharide antigens, polysaccharide antigens do not induce T-cell dependent immunity with memory cell production, and repeated boosting with MSPV4 has resulted in a blunting of antibody response, termed *hyporesponsiveness.*[22,136] In contrast, licensed conjugate vaccines have been shown to be immunogenic when used in an appropriate series with boosters, even in infants.[156] Conjugate vaccines produce stimulation of both T-cell and B-cell dependent immunity and have been shown to decrease nasopharyngeal carriage.[38] For these reasons, although meningococcal polysaccharide vaccines are licensed and available in many countries, meningococcal conjugate vaccines have significant advantages.

Meningococcal Vaccines in the United States

Meningococcal Polysaccharide Vaccine

Meningococcal polysaccharide vaccine (MPSV4, Menomune) is a capsular polysaccharide vaccine licensed for use in individuals older than 2 years of age who are at increased risk for meningococcal disease. This vaccine was licensed in 1981 and was the only meningococcal vaccine widely available in the United States until the licensing of meningococcal conjugate vaccines. Conjugate vaccines are generally preferred over meningococcal polysaccharide vaccines in people for whom conjugate vaccines are licensed.[38,43] However, meningococcal conjugate vaccines are not licensed for persons older than 55 years of age, so in this age group MSPV4 is the only U.S. licensed vaccine. MSPV4 is given subcutaneously as a single dose.

Meningococcal Conjugate Vaccines

Three meningococcal conjugate vaccines are currently licensed in the United States: MenACWY-D (Menactra), MenACWY-CRM (Menveo), and HibMenCY-TT (MenHibrix). MenACWY-D and MenACWY-CRM are quadrivalent vaccines that couple polysaccharide capsular antigens (i.e., serogroups A, C, Y, and W-135) to a protein carrier. In MenACWY-D, the protein carrier is diphtheria toxoid and in MenACWY-CRM, the protein carrier is CRM_{197} (mutant diphtheria toxin). MenHibrix is a combination *H. influenza* type B and bivalent meningococcal conjugate vaccine (i.e., serogroups C and Y) licensed in the United States for infants.

MenACWY-D, MenACWY-CRM, and HibMenCY-TT vaccines have been found to be safe and immunogenic in infants, children, adolescents, and adults.* Efficacy was inferred by the demonstration of development of serum bactericidal antibodies to each of the meningococcal antigens the vaccines contain at a level that was noninferior to the response generated by polysaccharide vaccines.[16,201]

Close monitoring for potential adverse events initially suggested a possible association between recent MenACWY-D (Menactra) and Guillain-Barré syndrome based on case reports through the Vaccine Adverse Event Reporting System (VAERS) shortly after the licensure of MenACWY-D.[6] Subsequently, the results of two large observational studies (collectively representing 2 million doses of vaccine) found no risk for Guillain-Barré associated with meningococcal conjugate vaccine.[1] Language about Guillain-Barré has been removed from the meningococcal vaccine information statement.

Meningococcal conjugate vaccines are administered intramuscularly (as opposed to MPSV4, which is administered subcutaneously). Soon after licensure of meningococcal conjugate vaccines, numerous cases of misadministration of MenACWY-D (Menactra) were reported. The CDC studied 100 such cases and found that misadministration of MenACWY-D by the subcutaneous route still resulted in a protective immune response. While this route of administration is not recommended, persons who received the vaccine by this route do not need to be revaccinated.[39]

The duration of protection of quadrivalent meningococcal vaccination was originally thought likely to persist for 10 years. This was part of the rationale to incorporate meningococcal conjugate vaccine into the U.S. preadolescent vaccine platform. It was presumed that by vaccinating 11- to 12-year-old children, antibody levels would be sufficient for protection through the early college years, when there is increased risk for meningococcal disease. Subsequent studies showed significant decline in meningococcal antibody (vaccine serogroups) in adolescents 3 to 5 years after vaccination. Additionally, a limited

*References 8, 16, 81, 98, 120, 156, 164, 210.

number of cases of meningococcal C or Y disease were reported to the CDC in previously vaccinated teenagers. The average time between vaccination and meningococcal disease was 3.25 years.[44,219] In 2010, as a result of concerns that adolescents may not be protected against invasive meningococcal disease for more than 5 years, the CDC's Advisory Committee on Immunization Practices (ACIP) recommended a booster dose of quadrivalent meningococcal vaccine be administered at age 16 years (Table 88-4).[44]

Meningococcal conjugate vaccines are currently licensed in the United States for persons as young as 9 months through 55 years. MenACWY-D is licensed in persons 9 months through 55 years; MenACWY-CRM is licensed in persons 2 through 55 years; HibMenCY-TT is licensed in infants and children 6 weeks through 18 months of age. As in adolescents, waning antibody has been detected 3 to 5 years after primary immunization and is the basis for the current recommendations for boosters if an ongoing risk factor exists for meningococcal disease (see Table 88-3).[44]

U.S. Recommendations for Use of Meningococcal Vaccines

Table 88-3 summarizes the ACIP recommendations for the use of vaccines to prevent meningococcal disease.[38,41,43,44,108] Meningococcal vaccine is recommended for all U.S. children (who have no contraindication) at the 11- to 12-year-old preadolescent visit, with a booster dose at age 16 years. Teenagers who receive their primary dose of meningococcal conjugate vaccine at 13 to 15 years should receive a booster at 16 to 18 years. If the primary dose of meningococcal conjugate vaccine is given on or after the 16th birthday, no booster is recommended. ACIP recommends use of quadrivalent meningococcal conjugate vaccines (MCV4; Menveo or Menactra) as the preferred products, but MPSV4 is an alternative.[16,38,44]

TABLE 88-4 **Recommendations for Meningococcal Vaccinations***

Targeted Group by Age and/or Risk Factor	Primary Series	Booster Recommendations
Persons ages 11-18 yr	Give one dose of MCV4,† preferably at age 11 or 12 yr[a]	Booster at age 16 yr if primary dose given at age 12 yr or younger Booster at ages 16-18 yr if primary dose given at ages 13-15 yr[b]
Persons ages 19-21 yr who are first-year college students and living in residence halls	Give one dose of MCV4[a] if person has never previously received MCV4 *or* if previous MCV4 given at age younger than 16 yr	No booster recommendations unless person has other risk factors for meningococcal disease (see specific categories in this table)
Travelers to or persons residing in countries where meningococcal disease is endemic or hyperendemic, persons in a defined risk group during an institutional or community outbreak,[c] and microbiologists routinely working with *Neisseria meningitidis*		
Ages 9-23 mo	Give two doses of MenACWY-D (Menactra), 3 mo apart[d]	If risk continues, give initial booster after 3 yr followed by boosters every 5 yr
Ages 2-55 yr	Give one dose of MCV4[a]	If risk continues, boost every 5 yr with MCV4[e,f]
Ages 56 years and older	Give one dose of MPSV	If risk continues, boost every 5 yr with MPSV[f]
Persons with persistent complement component deficiencies[g] or functional or anatomic asplenia		
Ages 9-23 mo with persistent complement component deficiencies only *(does not include children with functional or anatomic asplenia)*	Give two doses of MenACWY-D (Menactra), 3 mo apart	Initial booster 3 yr after completion of primary series, followed by boosters every 5 yr thereafter
Ages 9-23 mo with functional or anatomic asplenia (includes sickle cell disease)	Give two doses, 2 mo apart beginning at age 2 yr and ≥4 wk after completion of PCV13 vaccine[h]	Initial booster 3 yr after completing the primary series; thereafter boosters every 5 yr as long as child continues to be at risk
Ages 2-55 yr	2 doses of MCV4, 2 mo apart[h]	Boost every 5 yr with MCV4[e,i]
Ages 56 yr and older	Give one dose of MPSV	Boost every 5 yr with MPSV

Data from references 41, 43, 44, 108.
*Table adapted from Immunization Action Coalition. http://www.immunize.org/askexperts/experts_men.asp.
†MCV4; Menveo or Menactra
[a]If the person is HIV-positive, give 2 doses, 2 mo apart.
[b]The minimum interval between doses of MCV4 is 8 wk.
[c]Seek advice of local public health authorities to determine if vaccination is recommended.
[d]If child aged 9-23 mo will enter endemic area in <3 mo, give doses as soon as 2 mo apart.
[e]If primary dose(s) given when younger than age 7 yr, give initial booster after 3 yr, followed by boosters every 5 yr.
[f]Boosters are recommended if the person remains at increased risk.
[g]Persistent complement component deficiencies include C5-C9, properdin, factor H, and factor D.
[h]Children with functional or anatomic asplenia should complete a series of PCV13 vaccine before vaccination with MCV4; if MenACWY-D (Menactra) is to be given, begin meningococcal vaccination at least 4 wk after last dose of pneumococcal conjugate vaccine to avoid possible interference with immune response to the pneumococcal vaccine series.
[i]If the person received a one-dose primary series, give booster at the earliest opportunity, then boost every 5 yr.

Other persons at increased risk for meningococcal disease and recommendations for vaccine are listed in Table 88-3.

Meningococcal Vaccines Outside the United States

Meningococcal A Vaccine

The story of development and delivery of a conjugate serogroup A meningococcal vaccine to Africa is an inspirational public health achievement. Sub-Saharan Africa has long been afflicted with endemic and epidemic serogroup A disease. Approximately 430 million at-risk Africans reside in this "meningitis belt." Outbreaks of serogroup A meningococcal disease occur in the winter and are associated with dry Saharan winds and low humidity.[160] Every 7 to 12 years explosive outbreaks of disease occur, causing extensive morbidity and mortality. Control measures consisted largely of case identification and reactive mass immunization using a polysaccharide monovalent serogroup A meningococcal vaccine.

In 2001, a partnership was developed between the World Health Organization (WHO) and the Program for Appropriate Technology in Health (PATH) around the Meningitis Vaccine Project. This project was funded by the Bill and Melinda Gates Foundation, and its goal was to develop and introduce an affordable meningococcal conjugate serogroup A vaccine in Africa. The vaccine was developed with help from additional agencies at a cost of $0.40 per dose. Two studies (one in children 12 to 23 months of age and one in persons 2 to 29 years of age) showed the vaccine to be more immunogenic and with a similar safety profile to the polysaccharide serogroup A vaccine.[195] Burkina Faso became the first country to conduct a nationwide rollout of the meningococcal conjugate serogroup A vaccine MenAfriVac, nationwide. Over 11 million people ages 1 year to 29 years were immunized in a 10-day period in December 2010. During the subsequent 2011 winter dry season only 2665 suspected meningococcal cases were reported (80% reduction over prior years). From the suspect cases, 1437 specimens were cultured (or submitted for PCR), and only four isolates were identified to be serogroup A—all from unvaccinated individuals.[49] Carriage studies done before and after vaccine implementation in Burkina Faso show a decrease in oropharyngeal carriage. Before vaccine implementation, examination of 20,326 oropharyngeal cultures yielded a carriage rate of 0.4 percent. Fifteen thousand oropharyngeal samples obtained after the MenAfriVac implementation program revealed none of the samples were positive for serogroup A *N. meningitidis*.[42,125] More than 55 million Africans have now been vaccinated in at least 6 countries. Large-scale institution of this vaccine is estimated to dramatically decrease morbidity and mortality from serogroup A meningococcal disease in Africa in the next 10 years.

Meningococcal B Vaccines

Development of an immunogenic serogroup B meningococcal vaccine has been problematic because the polysaccharide capsule of meningococcus group B is poorly immunogenic in animals or humans. In 1983, Finnish investigators reported that horse antiserum to meningococcus group B reacted with glycoproteins isolated from human and rat brains.[17] Therefore, good immunogenic responses are not achievable with group B polysaccharide antigen vaccines because the body may see these antigens as "self" antigens (similar to neural tissue). Serogroup B outer membrane vesicle vaccines have been studied and used by some countries such as New Zealand to control outbreaks with moderate success.[84,119] However, outer membrane vesicle vaccines are largely directed against the PorA porin protein, which is antigenically variable among strains. Therefore, these vaccines are not broadly useful because strain variation occurs geographically.

A promising investigational multicomponent serogroup B vaccine contains antigens to factor H binding protein variant 1 (fHbpl), neisserial adhesion A (NadA) and *Neisseria* heparin binding antigen (NHBA) combined with outer membrane vesicles from a New Zealand strain (NZ98/254). This vaccine, referred to as 4CMenB, has been studied in clinical trials in several European countries. A large multicountry European study examined the immunogenicity and reactogenicity of 4CMenB in 1885 infants. The vaccine was highly immunogenic against two of the three meningococcal strains tested. For the third strain, 79 percent of infants developed sufficient antibody response that would be considered protective. Injection site pain and fever were relatively common after vaccination.[91] A study in more than 1600 Chilean adolescents showed that a two-dose series of 4CMenB performed better than a single dose in terms of good immunogenicity that lasted at least 6 months.[189]

The world awaits licensure and use of a highly immunogenic, safe vaccine with broad protection against multiple serogroup B meningococcal strains. Such a vaccine will have a substantial impact on control of serogroup B disease worldwide.

Meningococcal C Vaccines

Meningococcal C conjugate vaccination in the United Kingdom has demonstrated efficacy,[176,207] the ability to produce herd immunity (67% disease reduction in unvaccinated 1 to 17 year olds),[177] and a 66 percent reduction in adolescent nasopharyngeal carriage. A meningococcal serogroup C conjugate vaccine program was begun in the United Kingdom in 1999 with a 2-, 3-, 4-month primary series schedule for infants. Children 1 to 18 years of age received a single dose of meningococcal serogroup C conjugate vaccine (MCCV). In 2002, MCCV was offered to all individuals up to age 25 years. Later studies from the United Kingdom showed rapid waning of immunity in vaccinated infants (vaccinated at 2, 3, and 4 months). Despite high vaccine efficacy during the first year after immunization, vaccine efficacy fell significantly at 1 year or more after vaccination.[30] Subsequently, the infant vaccine schedule was changed to a two-dose primary series at 3 months and 4 months, with a booster dose given at 12 months of age.

The United Kingdom's meningococcal conjugate serogroup C program has been highly effective in producing a dramatic and sustained reduction in serogroup

C disease. The overall incidence rate of serogroup C disease has fallen by 98.7 percent in England and Wales, and no evidence exists for serogroup replacement.[29,138]

Several other countries also incorporated meningococcal C conjugate vaccines into their immunization programs because of circulating clonal serogroup C strains. Canada's staggered serogroup C vaccine implementation program allowed for a comparison of the meningococcal disease incidence in provinces with and without vaccine implementation; provinces with vaccine implementation showed substantial reduction in meningococcal C disease, and no serogroup replacement was seen.[15]

Future for Meningococcal Vaccines

A deeper understanding of the pathophysiologic mechanism of meningococcal disease and the bacterial structures critical for antigenicity and immunogenicity in humans is needed. A safe and effective vaccine that could induce protection against all encapsulated meningococci in all age groups is the ultimate goal.

CHAPTER 89

Gonococcal Infections

Charles R. Woods, Jr.

Gonorrhea, the foremost manifestation of human disease caused by *Neisseria gonorrhoeae* (the gonococcus), is one of the oldest known human diseases. Hippocrates called the disease "strangury" in the 5th and 4th centuries BCE. Galen coined the name *gonorrhea*, meaning "flow of semen," in the 2nd century CE. Greco-Roman physicians recognized the association of the disease with sexual activity and prescribed sexual abstinence plus washing of the eyes of newborns for treatment. Gonorrhea has been known as *clap* since the late 1300s. This term may have derived from the Les Clapier district of Paris, where prostitutes were housed during the Middle Ages.[196,241]

After syphilis appeared in Europe in the late 15th century, the two diseases were thought to represent different manifestations of the same infection, and they often coexisted then as today. The description by Neisser of *N. gonorrhoeae* in stained smears of urethral and other exudates in 1879 and culture of the organism by Leistikow and Löffler in 1882 provided the foundation for modern understanding of the clinical spectrum of gonococcal diseases. The advent of safe and effective antimicrobial agents, first sulfonamides in 1936 and then penicillin in 1943, was the next major advance in combating gonorrhea.[196,241] Modern knowledge of the molecular pathogenesis of *N. gonorrhoeae* infection began in 1963 with the observation by Kellogg and colleagues[199] that gonococcal strains with differences in colony morphology also varied in virulence. Further understanding of the clinical aspects of the disease was facilitated by development of the Thayer-Martin medium in 1964.[338]

N. gonorrhoeae remains a major international public health problem because of reproductive sequelae of infection (e.g., infertility), the ever-growing resistance to antimicrobial agents, and disproportionate case burdens in public clinics.[59,198,224,225,289] Efforts to develop an effective vaccine are ongoing.[82,315,361] Additional information on gonococcal infections is provided in Chapter 42.

EPIDEMIOLOGY

Gonococcal infections remain second in incidence only to *Chlamydia* infections among reportable diseases in the United States.[61,67,70] Rates of gonococcal infection in the United States, Canada, and western and central Europe declined steadily in the 1980s and 1990s. Rates recently have increased in the United States and Canada. In 2010, 100.8 cases/100,000 population were reported, a slight increase from 98.1 in 2009, which was the lowest reported rate in U.S. history. In Canada 33.1 cases/100,000

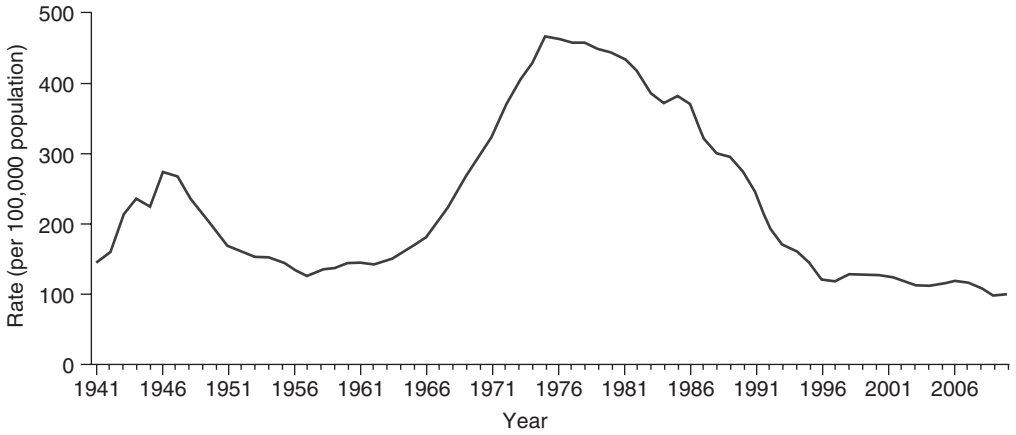

FIGURE 89-1 ■ Rates of gonorrhea in the United States, 1941 to 2010. After a 74 percent decline from 1975 through 1997, overall gonorrhea rates have plateaued in recent years. Gonorrhea is substantially underdiagnosed and underreported. (From Centers for Disease Control and Prevention: http://www.cdc.gov/std/stats10/gonorrhea-figs.htm.)

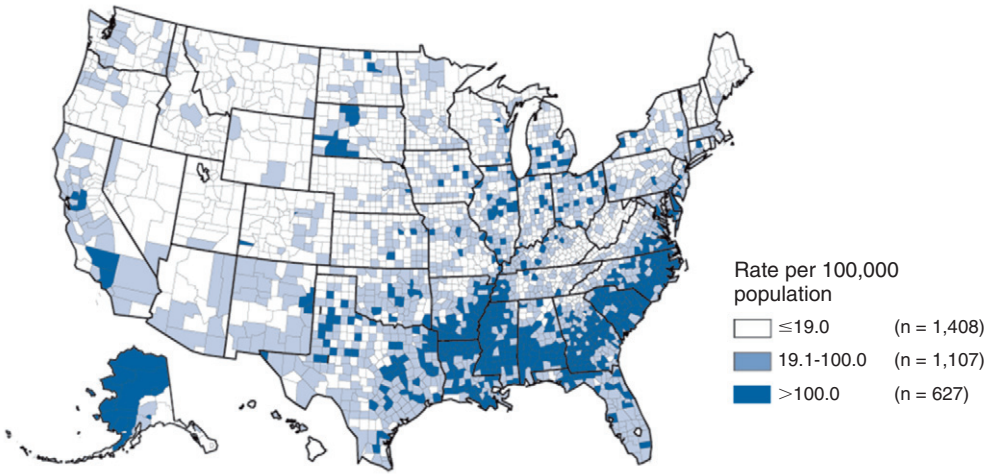

FIGURE 89-2 ■ Rates of gonorrhea by age and sex: United States, 2010. This pattern is the same as in previous decades. (See companion Expert Consult website for color version.) (From Centers for Disease Control and Prevention: http://www.cdc.gov/std/stats10/gonorrhea-figs.htm.)

population were reported in 2009, continuing an overall trend of increase from a nadir of 14.9 in 1996.[277] Regions with higher rates of adult disease have higher numbers of pediatric cases,[112,136] a finding that reflects the adult origin of virtually all pediatric cases.

An estimated 1 million new cases of gonococcal infection occur annually in the United States, only approximately a third of which are reported. At least half of the cases are thought to go undiagnosed or unreported. In 2010 in the United States, 309,341 cases were reported.[70] U.S. national trends in reported rates are shown in Figure 89-1. Rates of gonorrhea are based primarily on detection of symptomatic infection. Asymptomatic chronic infection in adults is well documented and may account for 5 percent of cases.[181] Such persons can transmit the infection. Some untreated cases will resolve over time. Data also indicate that asymptomatic infection occurs in children, including prepubertal children.[3,128,166,181] Gonococcal infections rarely are fatal (approximately four deaths per year in the United States), with death being caused by gonococcal sepsis.[61,225]

Gonorrhea rates remain highest among adolescents and young adults (Fig. 89-2). In 2010, the highest age group rates were 571/100,000 among adolescent females 15 to 19 years of age and 561 among males 20 to 24 years of age.[70] Rates among African Americans were 18.7 times higher than among whites (432 vs. 23). Low socioeconomic status, early onset of sexual activity, unmarried marital status, and past gonococcal infections are risk factors for acquiring gonococcal infection, as are prostitution and illicit drug use.[16,40] Limited access to quality health care also may contribute to an increased prevalence of disease in impoverished populations.[66] The prevalence of gonococcal infection in adolescents attending private clinics probably is lower than that in those seeking care in publicly funded settings.[22] For women, the use of hormonal contraceptives may increase the risk for acquiring infection, whereas the use of spermicides or diaphragms appears to be at least partially protective.[221,222]

Rates of gonococcal infection among men who have sex with men (MSM) are lower than in past years but remain higher than those among men who have sex only

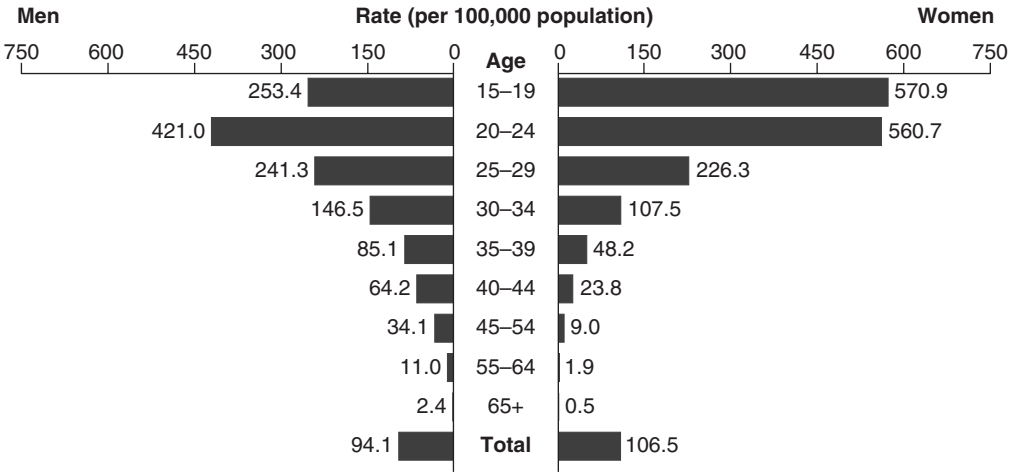

FIGURE 89-3 ■ Rates of gonorrhea by county in the United States and outlying areas, 2010. (From Centers for Disease Control and Prevention: http://www.cdc.gov/std/stats10/gonorrhea-figs.htm.)

with women (MSW).[70] The proportion of gonococcal infections among MSM versus MSW is higher in western states and New York City than in other regions of the United States. In a prospective study from 2001 to 2003, the prevalence of pharyngeal gonorrhea among human immunodeficiency virus (HIV)-negative MSM was 5.5 percent; 92 percent of cases were asymptomatic.[239]

The southeastern United States continues to have rates of gonorrhea higher than those of other regions of the country, but rates per 100,000 population in the Southeast fell from 175 to 134 between 2001 and 2010. Rates increased from 2009 to 2010 in the South, West, and Northeast but declined in the Midwest. About 50 percent of reported cases occurred in only 63 counties or independent cities in the United States in 2010 (Fig. 89-3). Most counties with more than 100 cases/100,000 population were located in the South.

Humans are the only reservoir of *N. gonorrhoeae*. Exudate and secretions from infected mucosal surfaces allow transmission to occur during the intimate contact of sexual acts, parturition, and, rarely, household exposure. The incubation period usually is 2 to 7 days. No evidence of airborne transmission of gonococci exists; contact with viable microbes is required for transmission. Gonococci survive on surfaces outside the human body for only short periods (probably minutes). Although organisms can be cultured from environmental sources (e.g., toilet seats) for up to 3 hours after artificial inoculation in large numbers, viable gonococci have not been recovered from random samplings in public restrooms.[139]

Nonsexual transmission of *N. gonorrhoeae* to the genitalia, rectum, or oropharynx of children rarely occurs and never should be presumed without extensive investigation of the social setting of the infected child.[252] Childhood infection potentially could be acquired when a child co-sleeps in the same bed with an infected family member,[139] and sharing of bath towels and other similar objects has been suspected as the cause of epidemics in prepubescent girls living together.[322] Although persistence of apparently perinatally acquired gonococcal infection for up to 1 year of age has been reported and fomite or maternal nonsexual transmission to young infants is plausible,[35] these possibilities should not be generalized beyond infancy. Gonococcal conjunctivitis can be acquired nonvenereally.[213]

The risk for males acquiring urethral infection after a single episode of vaginal intercourse with infected females is estimated to be 20 percent. With four exposures, the risk increases to 60 to 80 percent. The prevalence of infection in females named as sexual contacts of males with gonococcal urethritis has been reported to be 50 to 90 percent.[172,177]

The annual direct medical cost of treating sexually transmitted infections (STIs), including HIV, in the United States alone was estimated at $11 to $17 billion in 2003 U.S. dollars. Almost half of these costs accrue to persons aged 15 to 24 years. The reduction in gonorrhea and syphilis rates in the United States between 1990 and 2003 was estimated as being equivalent to $5 billion during this period.[79]

MICROBIOLOGY

Neisseria spp. are aerobic, gram-negative, nonmotile, non–spore-forming cocci that occur in pairs (diplococci), with adjacent sides flattened. They have the typical gram-negative microbial outer membrane overlying a thin peptidoglycan layer and cytoplasmic membrane. The species lacks a true polysaccharide capsule but produces a surface polyphosphate that provides a hydrophilic, negatively charged surface.[259] In Gram stains of clinical specimens, the microbes frequently are observed within phagocytes.[316]

Gonococci are able to use glucose, lactate, and pyruvate as carbon sources but cannot use other carbohydrates, which is the basis for the carbohydrate utilization tests for speciation of *Neisseria* (Table 89-1). Catalase and cytochrome oxidase are produced by the gonococcus, as in most *Neisseria* spp., but gonococci do not produce appreciable amounts of superoxide dismutase. Growth is optimal in a 5 percent carbon dioxide atmosphere at 35°

to 37° C (95° to 98.6° F) and a pH of 6.5 to 7.5. Gonococci do not survive below pH 6.0, grow poorly below 30° C (86° F), and do not survive above 40° C (104° F).

Neisseria spp. require enriched media, including free iron, to support their growth. Multiple colony types are evident when a single isolate is grown on clear agar. Small convex glistening colonies are piliated, whereas larger, flatter colonies are nonpiliated. In vitro passage usually results in loss of pili. Under low-power microscopy, some colonies appear opaque or granular and others are transparent. The former represent colonies in which most cells express one or more opacity-associated proteins (Opa), whereas in the latter colonies, most cells do not express these proteins.*

Culture from Clinical Specimens

The organisms are cultured best on chocolate blood agar in an atmosphere enriched by carbon dioxide. If the clinical specimen has been obtained from a highly contaminated site (e.g., rectum or cervix), a selective medium containing nystatin, vancomycin, trimethoprim, and colistin (e.g., modified Thayer-Martin medium) to suppress contaminating flora allows the growth of most *Neisseria* spp. A few strains of gonococci are inhibited by vancomycin (see later).[38,237] Chocolate agar without antimicrobial agents is preferred if the culture is taken from a usually sterile area such as blood, cerebrospinal fluid (CSF), synovial fluid, or a skin lesion. Gonococcal colonies usually are evident on agar plates within 24 to 48 hours after inoculation. Frequent propagation is necessary to maintain isolates because viability is lost rapidly after 48 hours of growth.

Because gonococci cannot tolerate drying, clinical specimens must be plated as soon as possible onto appropriate media. Transport bottles that contain medium and a carbon dioxide–enriched atmosphere should be used if definitive processing of the specimen must be delayed. Transport bottles should be maintained upright to preserve the carbon dioxide atmosphere.

*References 38, 43, 199, 323, 334, 335, 349.

In addition to sugar fermentation patterns (see Table 89-1) and oxidase positivity, other biochemical reactions can be used to differentiate between *Neisseria* spp. or confirm that an isolate is *N. gonorrhoeae*.[71] Enzyme substrate tests that identify the presence or absence of 1-hydroxyprolylaminopeptidase, γ-glutamyl aminotransferase, and β-galactosidase are available as an adjunctive means of confirmation.[99] Gonococci possess only the former. These reactions alone will not distinguish *N. gonorrhoeae* from several commensal *Neisseria* spp. Antigen-detection–based tests, including fluorescent antibody staining, also have been used to confirm the identity of an isolate as *N. gonorrhoeae*.[200] Tests based on detection of gonococcal nucleic acid sequences, which are being used increasingly for diagnostic purposes, can be used to confirm the identity of gonococcal isolates from cultures (see later discussion of diagnostic testing and medicolegal issues).

Genetic Characteristics

Gonococci have a circular chromosome consisting of 2219 kilobases (kb), which is about half the size of the *Escherichia coli* genome.[110] The gonococcal genome has approximately 2250 predicted open-reading frames.[36] The entire genomes of *N. gonorrhoeae* strains FA1090, NCCP11945, and ST1407 have been sequenced. A macrorestriction map with the positions of many genetic markers has been available since 1991.[82,167,269] More than 1300 open-reading frame sequences have been validated.[36]

Piliated gonococcal cells (the natural in vivo state) are competent for genetic transformation by exogenous DNA at all stages of growth.[26] Only homologous DNA is taken into the cell.[117] Gonococci are highly autolytic and release DNA in a biologically active form. Thus, different strains are able to exchange genetic material readily. Such exchange can lead to further genetic and phenotypic diversity, which helps maintain the species in its human hosts and facilitates transfer of chromosomal antibiotic resistance genes.[304]

A 36-kb conjugal plasmid is present in many gonococci. It efficiently mobilizes its own transfer and other

non–self-mobilizable plasmids (e.g., the 4.5- and 7.5-kb penicillinase plasmids), but not chromosomal genes.[254,266,292] Extrachromosomal, nonplasmid DNA circles recently have been identified in wild-type gonococcal isolates. They may play a role in gene recombination, amplification of chromosomal genes, and transformation.[18] Gonococci possess multiple restriction endonucleases and their corresponding DNA methylases.[333] The species is relatively nonmutagenic and lacks photoreactivation and error-prone repair systems.[48]

Strain Typing

The ability to differentiate one strain from another allows researchers to investigate the epidemiology of transmission of gonorrhea and assessment of virulence factors. Numerous methods have been applied to gonococci.

Auxotyping classifies strains according to their ability to grow or not grow in the absence of 11 specific compounds, including amino acids (e.g., arginine and proline), purines, pyrimidines (e.g., hypoxanthine and uracil), and other nutrients (e.g., thiamine). Approximately 20 auxotype phenotypes are recognized. Genetic studies have shown that multiple mutations in the same biochemical pathway can lead to the same phenotype, such that a single auxotype can represent many genotypes.[311] Auxotypes are stable in vitro, however, and organisms cultured from sexual partners are of a similar auxotype.[51,55] The auxotype of greatest epidemiologic importance is designated arginine-, hypoxanthine-, and uracil-negative (AHU^-). Such strains are unable to grow in the absence of these compounds. AHU^- strains typically are more resistant to killing by normal human serum, are more likely to cause asymptomatic infections in males, and are found more frequently in patients with disseminated infection.[121,201] AHU^- strains often are susceptible to vancomycin.[237]

Numerous serotyping schemes have been attempted,[72] but the best and most widely available serologic technique is based on antigenic heterogeneity of the porin protein (formerly called protein I) contained in the outer membrane of the gonococcus.[10,189,202,301,302] Two immunochemically distinct serogroups, PorA and PorB, exist and can be subdivided into serovars by using sets of monoclonal antibodies. Serovars remain stable in vitro and are designated IA-x or IB-x, where *x* is the numeral of the serovar. At least 26 IA and 31 IB serotypes have been identified.[63] Serotyping can be combined with auxotyping to further discriminate among gonococcal strains.[176,274] Limitations of auxotype-serovar classification include restricted supplies of reagents and batch-to-batch variation in monoclonal antibodies. In addition, common serovars can have such significant genetic diversity that this typing method may not provide sufficient discrimination for some epidemiologic evaluations.

Genotyping methods have been applied to *N. gonorrhoeae* in the past 2 decades.[219] Simple restriction endonuclease methods with rare cutting enzymes[126,275] have been supplanted by polymerase chain reaction (PCR)-based methods and pulsed-field gel electrophoresis (PFGE). Opa typing, which uses PCR primers to generate DNA bands from each of the 11 *opa* genes, followed by restriction enzyme digestion, provides discrimination that is similar to that of PFGE.[213] Sequencing of the *porB* gene also appears to be highly discriminatory among strains.[87] PCR amplification of the *porB* gene with restriction enzyme digestion provides discrimination similar to that of combined auxotyping-serotyping.[114] Repetitive-element sequence-based PCR (rep-PCR) correlates well with PFGE for analysis of gonococcal strains, is rapid, and can be performed directly from colonies without DNA extraction.[274,359] *N. gonorrhoeae* multiantigen sequence typing is based on internal variation of two highly polymorphic loci and has been evaluated for cluster identification, tracing sexual contacts, and investigating treatment failures.[340] Multilocus, variable-number tandem repeat analysis also has been developed for *N. gonorrhoeae*.[168] These methods appear most useful for local microepidemiologic purposes.

Multilocus sequence typing is the primary typing method used now for macroepidemiologic analyses such as monitoring global spread of clones or clonal complexes with particular virulence traits or antimicrobial resistance patterns. At least two seven-loci–based schemes have been developed.[340]

PATHOGENESIS

A continuously expanding body of literature is devoted to the pathogenesis of *N. gonorrhoeae*.* *N. gonorrhoeae* is well adapted to its human host and is able to co-opt components of the innate immune system for its survival. Species specificity is demonstrated by greater adherence of gonococci to human cells than to nonhuman cells. Close interactions of *N. gonorrhoeae* with mucosal cells, erythrocytes, spermatozoa, and polymorphonuclear cells are well described.

Gonococci are able to survive in the urethra in the face of hydrodynamic forces that tend to wash other microbes away and persist there despite close proximity and even attachment to the hordes of neutrophils that respond to their presence. These observations indicate an ability to adhere to mucosal epithelia and evade the host acute innate immune response. Individuals also can have repeated infections by the same gonococcal strain, suggesting that the organism can thwart establishment of local adaptive immune responses. The tissue damage that occurs in the fallopian tubes during salpingitis implies that one or more directly toxic moieties or factors can trigger a deleterious host response.[129,322]

In the male human model of experimental infection, gonococci are recovered in urine at low levels for about 2 hours after urethral inoculation. The microbes then disappear from the urine for variable periods before becoming shed in increasing numbers. The bacteriuria persists until signs and symptoms of dysuria and urethritis appear after an incubation period of 1 to 6 days after inoculation. Severity of symptoms does not correlate with the shed microbial burden. Pyuria and detectable urinary concentrations of interleukins (IL)-6 and IL-8 usually appear within 24 hours after inoculation.

*References 93, 98, 119, 127, 170, 218, 280.

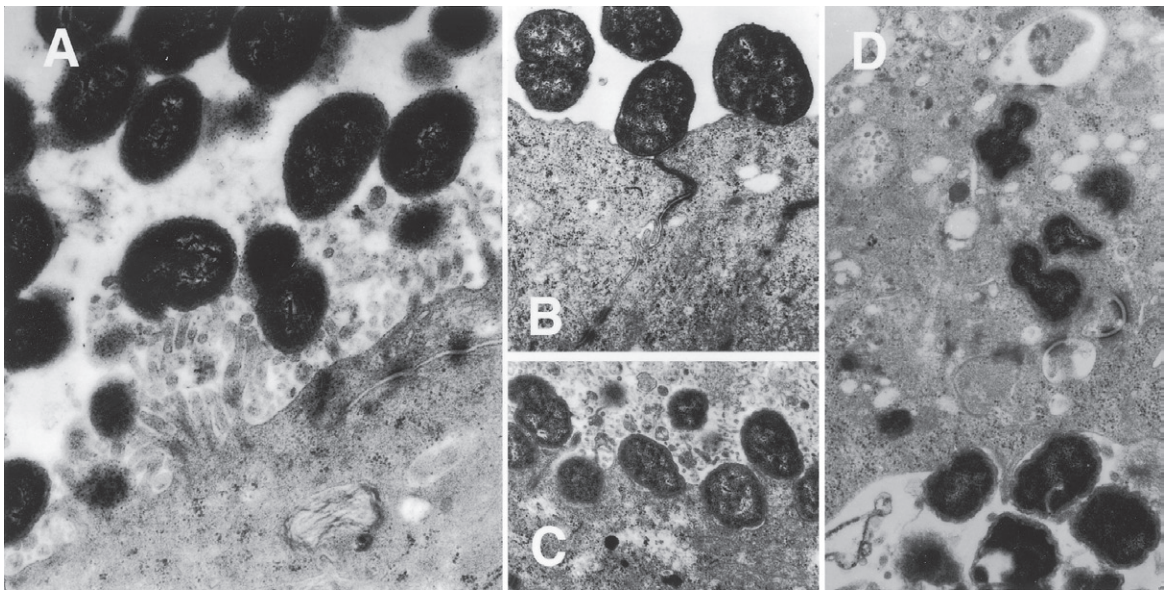

FIGURE 89-4 ■ Electron micrographs of *Neisseria gonorrhoeae* (strain MS11) interactions with polarized T84 human epithelial cell monolayers. At early stages of infection, the microbes adhere to the apical plasma membrane as microcolonies. Adherent bacteria are surrounded by a matrix of microvilli **(A)**. Bacteria subsequently disperse from the microcolony and adhere as a monolayer in which bacterial and host-cell membranes are tightly apposed **(B** and **C)**. The region of contact between the bacteria and the host-cell membrane enlarges **(C),** with subsequent internalization of the microbes **(D)**. Bacteria then traverse the host cell and exit via the basolateral membrane **(D).** (Photographs by Magdalene So, from the Annual Review of Cell and Developmental Biology, Volume 16. © 2000 by Annual Reviews. http://www.AnnualReviews.org.)

Phenotypic variation of gonococcal surface determinants is seen during the course of experimental infection.[170]

This human model and multiple in vitro molecular studies involving cell lines and fallopian tube organ cultures have provided many insights into the molecular pathogenesis of gonococcal infection.[84,165,227,228,285]

Resistance to Phagocytosis and Intracellular Killing

Gonococci are readily able to resist extracellular killing by neutrophils through mechanisms that are not completely understood. The microbes also resist phagocytosis via blocking deposition of opsonic antibodies and complement components on their own surfaces and by antigenic variation of their surface structures to evade any preexisting humoral immune responses. Antibody binding is inhibited by sialylation of surface lipo-oligosaccharide (LOS). Gonococci thwart the effects of complement via binding of the complement cascade inhibitor complement factor H to porin proteins and LOS.[98]

N. gonorrhoeae have multiple mechanisms by which they resist oxidative and nonoxidative killing after phagocytosis by neutrophils. The species produces catalase, cytochrome *c* peroxidase, superoxide dismutase, and a metalloproteinase that detoxify superoxide compounds produced in phagolysosomes. Gonococci also have repair systems for oxidatively damaged DNA. Nonoxidative antibacterial factors such as lysozyme, elastase, cathepsin G, defensins, and cathelicidins can be counteracted by gonococcal efflux pump systems, metalloproteinase, and other protein and regulatory systems.[98]

Invasion of Mucosal Epithelial Cells

In addition to the ability to resist killing by neutrophils, gonococci are able to persist in human hosts via their ability to invade epithelial cells. The initial steps of intracellular invasion involve attachment of microbes to epithelial cell surfaces through synergistic effects of pili, Opa proteins, and porin proteins.[19,98,151] Gonococci also exploit the production of complement factors, including C3, by cervical epithelial cells. In females, especially during the luteal phase and menses, C3 is secreted into the extracellular milieu, where it is activated to C3b. The gonococcal surface binds C3b and cleaves it to iC3b (inactive), which then serves as a ligand for the complement receptor 3 molecules on host cells that facilitates microbial attachment independently of pili and Opa proteins (see later).[119]

After adhering to host epithelial cells, some microbes are internalized by endocytosis triggered by interaction of gonococcal phospholipase D with host cell Akt (protein kinase B).[119] The vast majority of invading gonococci are ingested and killed by neutrophils. Gonococci are susceptible to the oxidative burst products of phagocytes, as well as to nonoxidative products such as cathepsin G.[52,308] Those that survive intracellularly may replicate inside the phagosomes and ultimately exit the basal (but not lateral) surface of the cell via exocytosis[228,232,250] (Fig. 89-4). Adjacent nonepithelial cells are sloughed, probably because of the toxicity of LOS and peptidoglycans.[149] Mucosal cell damage and submucosal invasion are followed by an influx of neutrophils along with the formation of submucosal microabscesses and exudation of purulent material into the lumen of the infected organ.[357]

Adherence of gonococci to mucosal epithelial cells causes activation of nuclear factor-κB (NFκB) and activator protein 1, which in turn leads to upregulation and release of multiple cytokines and chemokines, including macrophage colony-stimulating factor, tumor necrosis factor-α (TNF-α), tumor growth factor-β (TGF-β), monocyte chemoattractant protein 1, IL-1β, IL-6, and IL-8.[251,279]

N. gonorrhoeae can form biofilms during cervical infection. Membrane blebs that contain DNA elements and outer membrane structures are key components of these biofilms. A gonococcal thermonuclease is involved in remodeling of biofilm matrix. Cells in the biofilm activate gene sets involved in anaerobic respiration.[127]

Other specific microbial virulence factors are discussed in the following sections.

Virulence Factors

Specific *N. gonorrhoeae* virulence factors include (1) pili, (2) opacity proteins, (3) porin protein, (4) the ability to survive in low iron environments, (5) immunoglobulin (Ig)A protease, (6) LOS, (7) cell wall peptidoglycan, (8) reduction modifiable protein (Rmp), and (9) a type IV secretion system. Many other gonococcal gene products and molecular systems have been identified, and a more detailed and complex understanding of virulence at the molecular level is steadily forthcoming.

Pili

Gonococci are piliated predominantly in vivo and express type IV pili. Pili cover essentially the entire surface of the cell and are arranged in individual fibrils or fibrillar aggregates. Pili consist primarily of polymers of an 18-kd subunit now denoted as PilE. A single pilus is approximately 6 nm in diameter and up to several microns in length.[232] Each may contain thousands of PilE subunits.[44] The PilC protein is present in lower numbers in the pilus but appears to be the key pilus adhesin. PilC interacts with CD46 molecules, which are present on most human cells and serve as receptors for C3b, C4b, measles, and other viruses. PilC-CD46 attachment appears to be a key step in the initiation of microbial adherence to host cells.[46,195,204,296,298]

Binding of pili to a host-cell membrane induces at least two responses in the host cell: release of Ca^{2+} from intracellular stores[194] and cytoskeletal rearrangements with the formation of cortical plaques that represent an accumulation of actin, ezrin, and other phosphotyrosine-containing proteins.[233,283] The latter results in elongation of the microvilli that embrace the microbe. Formation of plaque appears to be induced by retraction of the attached pilus, and retraction depends on another pilus protein designated PilT.[234]

Gonococcal pili undergo both phase variation (switching from piliated to nonpiliated states) and high-frequency antigenic variation.[45] These variations occur during natural infection and in vitro passage.[306] Pili have a common N-terminal domain, semi-variable domains in the midportion, and two hypervariable regions in the carboxyl-terminal of the pilin protein subunit.[324] Relatively invariant regions occur between the variable domains. The pilin protein consists of 159 to 160 amino acids. A disulfide bridge is formed by cysteine residues at amino acids 121 and 151.

The genetic mechanism of pilus antigenic variation has been studied extensively. The chromosome contains either one or two complete pilin genes. The expressed gene contains an intact promoter region, a ribosome binding site, and a seven–amino acid signal sequence in addition to the pilin sequence. Scattered around the chromosome are six to eight loci that contain varying portions of the pilin sequence without the promoter region or the 5′ end of the structural gene. Some loci may contain many incomplete pilin sequences arranged head to tail that differ slightly from one another. Movement of these sequences into the active expression site through nonreciprocal combination events results in antigenic variation of the pilus protein. If recombination leads to a faulty pilin subunit product that cannot be processed into a mature pilus, the progeny of that organism become nonpiliated (phase variation). Subsequent recombination events can allow reversion back to the piliated phase.*

In addition to promoting adhesion to epithelial cells, pili also provide a twitching motility, are involved in DNA transformation, and may play a role in resistance to ingestion by phagocytic cells.[232] The presence of pili, perhaps mediated through their promotion of adhesion, affects the activation of $CD4^+$ T-lymphocytes and the production of IL-10. This property may help gonococci diminish the T-cell response to their presence.[271]

Opacity-Associated Proteins

Opa proteins also influence adherence of the gonococcus to host cells. The isolation of particular Opa protein phenotypes from different anatomic sites or at different times during the menstrual cycle has suggested that these proteins contribute to the ability of the organism to succeed in a given niche. Opa proteins (formerly designated protein II) are a set of as many as 12 related proteins that are variably present in gonococcal outer membranes. Opa proteins are 24 to 28 kDa in size and confer increased opacity to colonies of organisms by promoting adherence of the organisms to one another. A given strain has the capacity to make at least 10 different Opa proteins but appears to express no more than 5 at the same time. Some cells express no Opa proteins. Like pili, Opa proteins undergo both antigenic and phase variation. Both types of variations can occur within a single colony, so sector variations in opacity can be seen.[28,322,334,335]

Each *opa* gene is present as a complete gene with its own promoter and is transcribed at all times. Phase variation in expression occurs at the translational level. Each gene has a varying number of pentameric CTCTT repeat units adjacent to the ATG start codon. When the number of repeats is divisible by three, the transcribed mRNA is

*References 158, 235, 236, 256, 305, 324, 336.

translationally in frame and the Opa protein is expressed. The number of pentameric repeats is subject to high-frequency variation. Antigenic variation results from recombination between the two hypervariable regions in each of the *opa* genes.[88,325-337]

Two classes of host-cell receptors for Opa proteins have been identified. Heparan sulfate–proteoglycan (HSPG) receptors are present on epithelial cells and interact with one particular Opa protein variant (Opa_{50}). HSPG binding can stimulate the lipid hydrolysis enzymes phosphatidylcholine-specific phospholipase C and acid sphingomyelinase and thereby lead to clathrin-independent endocytosis. HSPG-Opa binding also can lead to interactions with serum factors such as vitronectin and fibronectin, which then mediate endocytosis via host-cell integrin receptors. The CD66 family is present on epithelial cells and neutrophils, recognizes many different Opa proteins, and mediates nonopsonic phagocytosis, a process distinct from antibody- and complement-mediated phagocytosis.*

Porin Protein

Formerly designated protein I, porin protein is the most common gonococcal outer-membrane protein. Porin is 34 to 36 kDa, is exposed on the surface, exists as a trimer in the membrane, and is physically proximate to LOS and Rmp.[29,169] The trimer forms an anion-specific pore in the bacterial membrane that allows small water-soluble molecules to enter the cell.[360] The *por* locus has two alleles that encode chemically and immunologically distinct classes of porin protein—PorA and PorB—that are similar to porin proteins in other gram-negative bacteria. A given strain expresses only PorA or PorB, and many antigenic variants of both exist (thereby forming the basis for serotyping).[50,202]

The porin trimer appears to translocate into the host-cell membrane and is able to disrupt neutrophil degranulation, the oxidative burst, and phagosome maturation,[159,220,242] in addition to induction of apoptosis in epithelial cells and neutrophils in vitro.[246] Exposure to gonococcal porin protein induces the typical structural and biochemical changes seen in apoptotic cells.[245] Porin translocation permits rapid influx of Ca^{2+} into the host cell from the external environment.[246] Porin proteins also may play a role in endocytosis mediated by the binding of HSPG and Opa protein[19] and in downregulation of complement by binding with C4b-binding protein.[278]

Iron Metabolism

Iron is an essential nutrient for *N. gonorrhoeae*, and, in host tissues, iron is sequestered in hemin compounds as ferritin or is bound to lactoferrin or transferrin. The species does not produce any siderophores but relies on an iron-repressible system that scavenges iron from transferrin, lactoferrin, and hemoglobin. This system comprises numerous proteins, some of which serve as receptors for the aforementioned iron-bearing ligands.[24,76,92,351] Other components include a TonB-dependent transporter and an associated lipoprotein that are expressed ubiquitously by gonococci, have limited antigenic variability, and are important for growth in vivo.[93] These proteins thus have potential as vaccine targets.

Immunoglobulin A Protease

All gonococci (and meningococci, but not nonpathogenic *Neisseria* spp.) make a protease that cleaves both serum and secretory IgA1 (but not IgA2) at the hinge region with the release of Fab and Fc fragments. This protease may help the organism evade host IgA at the mucosal surface, especially early in secondary infections, when preexisting antibodies may be present. However, mutant strains without the IgA protease have limited ability to grow inside epithelial cells. The protease appears to cleave a host-cell intracellular protein (LAMP1) involved in phagosome compartmentalization.[215] IgA1 protease is not required for gonococci to cause experimental urethritis,[188] thus suggesting that its intraphagosome function may be more important in pathogenesis.

Lipo-Oligosaccharide

Gonococci express LOS complexes of 3 to 7 kDa on their cell surface. LOS consists of a lipid A moiety and a core polysaccharide comprising ketodeoxyoctanoic acid, heptose, glucose, galactose, glucosamine, galactosamine, or any combination of these constituents.[153] The lack of a long polymeric sugar attached to the core distinguishes LOS from the lipopolysaccharides of other gram-negative bacteria. The core sugar antigens of LOS are subject to intrastrain and interstrain variation, and a single strain may express as many as six variants of LOS.[108,152] Numerous genes are involved in LOS synthesis; these genes undergo high-frequency phase variation similar to *opa* genes.[146] LOS terminal sugars mimic the structure of certain human glycosphingolipids.[153]

Gonococci with predominately short LOS molecules appear to be more sensitive to killing by human serum but also more able to invade eukaryotic cells. Strains with longer LOS are more serum-resistant but noninvasive.[347] Longer LOS moieties are sialylated readily with host neuraminic acid by a bacterial sialyltransferase that appears to shield both LOS and porin molecules from antibody binding, thus providing protection from complement-mediated killing in serum.[34,352]

LOS from serum-sensitive strains is able to activate the classic complement pathway and may do so in the absence of antibody.[309] LOS induces the production of cytokines (i.e., TNF-α, IL-1β, IL-6, and IL-8) by urethral epithelial cells[162] and can mediate host defensin-enhanced adherence to epithelial cells.[145]

Cell Wall Peptidoglycan and Lytic Transglycosylases

Gonococci shed membrane fragments with peptidoglycan into their environment during exponential growth. Peptidoglycan monomers have numerous biologic

*References 105, 106, 147, 207, 231, 232, 346.

properties, including activation of complement and modulation of mononuclear cell proliferation. These fragments also damage fallopian tube mucosa in organ culture, thus suggesting a pathogenic role for the compounds in invasive disease.[149,228] Production of peptidoglycan monomers is a by-product of lytic transglycosylases that act during cell growth and division. At least five such enzymes are encoded by *N. gonorrhoeae*. These also may facilitate gene transfers as part of type IV secretion.[74]

Reduction Modifiable Protein

Rmp (formerly designated protein III) is an antigenically conserved, 30- to 31-kDa protein that is present in all pathogenic *Neisseria*. Rmp is located proximate to LOS and porin in the outer membrane. Antibodies that bind to Rmp epitopes block the bactericidal effect of the complement-fixing IgM antibodies that recognize LOS. Women with preexisting anti-Rmp antibodies appear to be more susceptible to the development of infection than do those without such antibodies.[287,288,322]

Ribosomal Protein L12

Ribosomal protein L12 mimics the structure of human chorionic gonadotropin, the natural ligand for lutropin receptors. It is able to bind to lutropin receptors in the upper female genital tract, which may facilitate ascending infection in females.[118,326]

Type IV Secretion System

About 80 percent of *N. gonorrhoeae* strains encode a horizontally acquired 57-kb genetic island that encodes a type IV secretion system (T4SS). A T4SS is a multiprotein complex that functions as a conjugation system. In gonococci the T4SS secretes single-stranded chromosomal DNA into the extracellular environment. T4SS expression may enhance microbial survival inside human cells in addition to its role in genetic recombination and natural transformation among gonococcal strains.[280]

Characteristics of Strains Causing Disseminated Disease

The increased virulence of some strains is suggested by observations such as a microepidemic of gonorrhea involving one asymptomatic infected male and eight female contacts.[161] Seven of the women were infected symptomatically, and four experienced disseminated infection. Overall, many infections are asymptomatic and dissemination is relatively rare.

Strains of *N. gonorrhoeae* obtained from adult patients with disseminated disease usually are less susceptible to the bactericidal activity of sera[39,83,285,286,310] (see earlier discussion of LOS). These strains have an atypical growth pattern on agar[238] that reflects the absence of Opa protein expression, which suggests that the genetic variation capacity described earlier allows adaptation to different niches and probably helps organisms elude the host response.[23] Unlike most gonococcal strains, many invasive strains (designated AHU$^-$) require arginine, uracil, and hypoxanthine for growth.[199] A high degree of sensitivity to penicillin also has been characteristic of most strains from patients with disseminated disease.[356] Many also are susceptible to vancomycin, which may prevent detection in selective media. These strains should be detected in the usual media used for blood culture.

Host Response

The adult response to local and systemic infection with *N. gonorrhoeae* has been investigated extensively, but no such studies have been performed on infected children. Gonococcal infections usually are characterized by intense inflammation that involves neutrophilic and mononuclear granulocytes. The vast majority of gonococcal cells ingested by neutrophils are killed.[52] Gonococci are susceptible to the oxidative products produced by neutrophils but also can be killed efficiently by nonoxidative products such as cathepsin G.[308]

An intact complement system is essential for successful eradication of the organism. Properdin-mediated recruitment of C4b-binding protein facilitates antibody-mediated complement-dependent killing of gonococci that resist destruction via the classic complement pathway.[155] Persons with inherited or acquired complement deficiencies may be predisposed to contracting disseminated gonococcal infection, as is the case with meningococcal infection. Approximately 13 percent of patients with disseminated disease have complement deficiencies.[123,259]

Adherence of gonococci in vitro induces the activation of NFκB and activator protein 1, which leads to upregulation of messenger RNA (mRNA) and release of numerous cytokines and chemokines: macrophage colony-stimulating factor, TNF-α, TNF-β, monocyte chemoattractant protein 1, IL-1β, IL-6, and IL-8.[251] Intraurethral challenge leads to increased levels of IL-8, IL-6, and TNF-α in urine before the onset of symptoms and in plasma at the onset of symptoms.[279]

Multiple episodes of gonorrhea may occur in a single individual in a short period and even may be caused by the same strain. The antigenic diversity and ease of altering the antigenicity of both pili and opacity proteins undoubtedly contribute to the insufficiency of the host response in preventing reinfection. Noninvasive mucosal infections elicit production of low-affinity, broadly reactive IgM antibody by IgD$^+$, CD27$^+$ B cells in a T cell–independent manner that may partially explain the limited humoral response to typical infections.[321] In a mouse model of vaginal infection, gonococci induce Th17 inflammatory responses, which drive neutrophil influx. Th1- and Th2-adaptive specific antibody responses are suppressed by increased production of TGF-β plus enhanced development of T-regulatory cells. TGF-β production is mediated by interaction of Opa proteins with carcinoembryonic antigen related–cellular adhesion (CEACAM) molecules on human cells.[218]

Circulating humoral antibody to the infecting strain is measured by an assay of bactericidal antibody and is present in most persons who have prolonged mucosal colonization with *N. gonorrhoeae*.[182,197] In addition, women in whom pelvic inflammatory disease (PID) develops

usually produce bactericidal antibody during the infection. IgA- and IgG-blocking antibodies against some gonococcal antigens appear to block killing of the bacteria mediated by otherwise bactericidal IgG and IgM antibodies (see earlier discussion of Rmp).[285] Serum antibody responses are greater in patients with invasive disease (e.g., bacteremia or salpingitis).

Secretory IgA antibody is present in the urethral exudate of men with gonorrhea and in the genital secretions of women with gonorrhea.[260] The development of local IgA antibody occurs more rapidly and is more transient than development of the serum bactericidal response. Microbial IgA1 protease is not required for infection but may play a role in reinfection.

A cellular immune response to gonococcal antigens in patients with uncomplicated gonorrhea has been demonstrated in vitro.[210] The significance of this response in controlling or preventing infection is unknown.

PERINATAL GONOCOCCAL INFECTIONS

Since the 1970s, health clinics have encouraged the routine screening of sexually active women for gonorrhea. Such screening is especially important during pregnancy. Adolescent girls have a higher prevalence of gonorrhea than do older women of child-bearing age. This probably translates into higher rates of gonorrhea in pregnant adolescents. Rates of gonococcal infection in neonates reflect the frequency of infection in pregnant women. Recognition of gonorrhea early in pregnancy identifies a population at risk who should be monitored sequentially for reinfection throughout pregnancy.[190]

The spectrum of infection with *N. gonorrhoeae* appears to be similar in pregnant and nonpregnant women. Most are asymptomatic. Pharyngeal infection seems to occur more commonly during pregnancy, perhaps reflecting altered sexual practices. One study reported that 39 percent of patients with *N. gonorrhoeae* at any site had concurrent involvement of the pharynx and that 30 percent had pharyngeal infection as the sole manifestation.[91] In adolescent girls, pregnancy and menstruation are associated with disseminated disease.[171]

Gonorrheal infection puts both the mother and infant at risk for the development of other forms of gonococcal disease. Pregnant women have an increased risk for the development of gonococcal septic arthritis, and most such cases occur during the third trimester or in the immediate postpartum period.[41,171] Although the incidence of gonococcal arthritis is low, many cases have occurred in pregnant adolescents.

Gonococcal PID and acute salpingitis also may complicate the pregnancy of an infected woman.[137] These complications usually occur during the first trimester and have been associated with a high rate of fetal loss. An increased incidence of postpartum fever in women with untreated gonorrhea likewise has been noted. A new mother with complications of peripartum gonorrhea may have difficulty providing care for her child.[185]

Hazards to the fetus posed by maternal gonorrhea include septic abortion, perinatal death, prematurity, perinatal distress, and premature rupture of membranes. Prolonged rupture of membranes, premature delivery, chorioamnionitis, funisitis, and a clinical diagnosis of sepsis occur frequently in infants with *N. gonorrhoeae* detected in the gastric aspirate during delivery.[7,120,162,293] Table 89-2 tabulates the proportions in six studies of infants born to infected mothers who experienced these problems. A controlled study conducted in an area with a high prevalence of gonorrhea found that maternal infection with *N. gonorrhoeae* was associated significantly with preterm birth and that 14 percent of preterm births in this population were attributable to gonococcal infection.[122]

Gonococcal Ophthalmia Neonatorum

Epidemiology

The increased risk for ophthalmia neonatorum among infants born to women with vaginal discharge has been recognized for centuries. Recommendations for flushing the eyes of a newborn commonly were given before the 20th century.[230] In the late 1800s, Neisser helped establish the relationship between the gonococcus and neonatal ophthalmia.

TABLE 89-2 **Pregnancy Complications and Outcomes of Mothers Who Were Infected with *Neisseria Gonorrhoeae* at Delivery**

Pregnancy Complications and Outcomes	Charles et al[75] (*N* = 14)* (%)	Sarrel and Pruett[303] (*N* = 37) (%)	Israel et al[185] (*N* = 39) (%)	Amstey and Steadman[7] (*N* = 222)* (%)	Edwards et al[120] (*N* = 19)* (%)	Handsfield and Holmes[161] (*N* = 12)* (%)
Normal or term infant	—	13 (35)	30 (77)	142 (64)	7 (37)	—

Premature rupture of membranes	6 (43)	8 (22)	—	52 (23)	12 (63)	9 (75)

*Data were provided in which the outcomes of pregnancies of mothers not infected with *N. gonorrhoeae* were shown to be significantly more favorable.

By 1881, Dr. Carl Sigmund Franz Credé recognized that asymptomatic disease in the mother was a potential source of infection.[97] Gonorrhea was highly prevalent in Europe, and Credé described an increased incidence in patients from lower socioeconomic backgrounds. Mechanical cleansing of the birth canal failed to protect the infant from gonococcal ophthalmia neonatorum (GON), which was occurring in approximately 10 percent of newborns in major cities. The infection was the cause of a large proportion of admissions to schools for the blind.[17] Credé described the technique of instillation of 2 percent silver nitrate into the infant's conjunctival sac, which remains one method recommended for preventive procedures today.

By 1930, most states in the United States required that all newborns receive silver nitrate prophylaxis (i.e., the Credé procedure). At present, prophylaxis of some form is required by most states. GON decreased as a cause of admission to schools for the blind in the United States, from an average of 24 percent from 1906 to 1911 to 0.5 percent from 1951 to 1955.

The worldwide decline in adult gonorrhea in the 1950s probably contributed to the decreased recognition of disease in newborns during that period. The incidence of GON rose in the 1960s and 1970s along with the increased incidence of gonorrhea in the general population and was very high in some developing nations.[207] In Los Angeles, California, the rate rose from 9/100,000 live births in 1957 to 1958 to 56/100,000 live births in 1962 to 1963. In a New York hospital between 1970 and 1973, a rate of 145/100,000 births was reported; in a hospital in North Carolina during 1969 and 1970, a rate of 265/100,000 live births was proved by culture.[320] In the late 1970s and 1980s, GON again subsided in developed countries but has remained a problem in underdeveloped nations.

Factors associated with higher rates of GON include lower socioeconomic class of the mother and longer duration of rupture of membranes before delivery.[11] An increased incidence of GON in infants of unwed mothers and mothers who have not had prenatal care also may exist.[317] Previous treatment of gonorrhea during pregnancy also is associated with an increased incidence of GON.[190] The incidence of prematurity in infants with GON often is reported to be higher. Whether this is due to an adverse effect of gonorrhea on the pregnancy or because GON may be recognized more readily in premature infants has not been established. Premature rupture of membranes appears to increase the risk for GON.

Prevention

In the United States, prophylaxis for GON is recommended for all infants immediately after birth and is required by law in most states. This is considered a grade A recommendation by the U.S. Preventive Services Task Force.[343] Prophylaxis regimens using a 1 percent solution of silver nitrate, 1 percent tetracycline ointment, or 0.5 percent erythromycin ophthalmic ointment are equally effective. In the United States, erythromycin 0.5 percent ophthalmic ointment is the only one of these agents available for prophylaxis of GON. Single-dose units are preferred over multidose tubes. One unit should be instilled into the eyes of every neonate as soon as possible after delivery. Instillation may be delayed for as long as 1 hour to facilitate parent-infant bonding.

During a shortage of erythromycin ointment in 2009, azithromycin and gentamicin ophthalmic preparations were recommended. In one institution, 4/662 (0.6 percent) of newborns treated with gentamicin 0.3 percent ophthalmic ointment developed reactions with eye discharge, eyelid erythema, blistering, and edema within 48 hours of administration.[249] Povidone-iodine 2.5 percent solution may be effective for prophylaxis of GON but is not approved for this use in the United States at this time.[343] In randomized trial versus 1 percent tetracycline ointment, povidone-iodine 2.5 percent solution was less effective overall in preventing ophthalmia neonatorum of any type and more often was associated with chemical conjunctivitis.[101] Bacitracin is not effective for prevention of GON.[148]

The efficacies of tetracycline and erythromycin preparations in the prevention of tetracycline-resistant *N. gonorrhoeae* ophthalmia are unknown.[261] Both probably are effective because of the high concentration of drug in these preparations. Studies of these agents for prevention of *Chlamydia trachomatis* ophthalmia have been conflicting. Povidone-iodine may be more effective in preventing *C. trachomatis* ophthalmia than either topical silver nitrate or erythromycin. None of these agents prevents chlamydial colonization of the nasopharynx.

Silver Nitrate and Gonococcal Ophthalmia Neonatorum

Numerous studies have compared the efficacy of silver nitrate and no prophylaxis or prophylaxis with another agent in the prevention of GON.[77,240,294] Such studies, though not randomized, involved large numbers of infants and consistently showed lower rates of GON in treated versus untreated infants. Decreased frequency of blindness from GON in the population during the last half century, even during periods of increased rates of gonorrhea in women of child-bearing age, further supports the benefits of silver nitrate prophylaxis.

In a randomized trial of Kenyan infants born to mothers with gonorrhea reported in 1988, rates of GON were 42 percent in the control group, 7 percent in the group treated with 1 percent silver nitrate (83% reduction), and 3 percent in the group treated with 1 percent tetracycline (93% reduction). The two treatment arms were not statistically different.[209] In a randomized trial in the United States involving infants born to women without gonococcal infection, infants treated with 1 percent silver nitrate had a 39 percent lower rate (statistically significant) of conjunctivitis of any type in the first 2 months of life than did infants who received no prophylaxis. Infants treated with 0.5 percent erythromycin ointment in this trial had a 31 percent reduction in contrast to control infants, but this result was not statistically significant.[20]

The major advantages of the use of silver nitrate for prophylaxis are the lack of allergic potential, the absence of development of bacterial resistance to the compound, and very low cost. Two outbreaks of erythromycin-resistant staphylococcal conjunctivitis in newborn nurseries have been associated with the use of erythromycin eye ointment as ocular prophylaxis, but the outbreaks remitted when silver nitrate was substituted. Disadvantages include the occurrence of conjunctival irritation with associated development of exudate in many neonates. A solution of silver nitrate that becomes concentrated may cause ophthalmic injury, but this problem largely has been alleviated by dispensing doses in ampules, which prevents evaporation.

Failure of silver nitrate prophylaxis (as well as other agents for prevention of GON) does occur. Improper administration of silver nitrate such that the solution does not reach the conjunctival sac, irrigation performed too quickly after instillation, and inadvertent omission of prophylaxis can lead to apparent failure. When gonococcal infection of the eye has become established before birth, silver nitrate is not expected to prevent further progression. The increased risk for GON associated with premature rupture of membranes is due to exposure to and establishment of infection before actual delivery. In some cases of premature rupture of membranes, clinically apparent GON can be present at the time of birth.

Despite these problems, the use of 1 percent silver nitrate remains a widely accepted, carefully evaluated, and safe form of GON prophylaxis. The occasional failure of silver nitrate prophylaxis emphasizes that it is preferable to prevent GON through identification and treatment of pregnant women.

Clinical Features

The newborn eye is subject to colonization with numerous bacterial organisms that cause infections that usually are clinically mild, nonprogressive, and characterized by conjunctival discharge. The bacteria most commonly associated with conjunctival discharge are *Haemophilus influenzae*, *Streptococcus pneumoniae*, *Staphylococcus aureus*, *Neisseria cinerea*, *Klebsiella pneumoniae*, enterococci, and *C. trachomatis*.[113,206] Viral causes include herpes simplex virus and adenoviruses. In contrast, infection of the eye of a newborn with *N. gonorrhoeae* results in disease of a severity that, despite frequently being mild, can be rapidly destructive and lead to scarring and blindness. The chemical conjunctivitis that can result from silver nitrate prophylaxis typically starts within 6 to 24 hours after administration and disappears within 24 to 48 hours.

Colonization during delivery is followed by an incubation period of 2 to 5 days and usually less than 3 days, but cases occasionally may be recognized for 2 to 3 weeks after delivery.[135] A discharge typically develops that initially is watery but usually becomes thick and mucopurulent within a short time and may contain blood (Fig. 89-5). The disease generally is bilateral. Early findings include prominent edema of the conjunctivae and lids, followed by edema and later ulceration of the cornea or spread to wider areas in severe cases. Rapid arrest of the disease is essential because the degree of corneal involvement determines whether vision will be preserved. Some cases are self-limited and have benign outcomes, and occasional cases of asymptomatic GON have been discovered during routine screening.[273] Perforation of the globe and panophthalmitis can result from extensive local disease. The conjunctivae may serve as a portal of entry for gonococcal septicemia, arthritis, or other manifestations of invasive disease, but such events seldom occur.

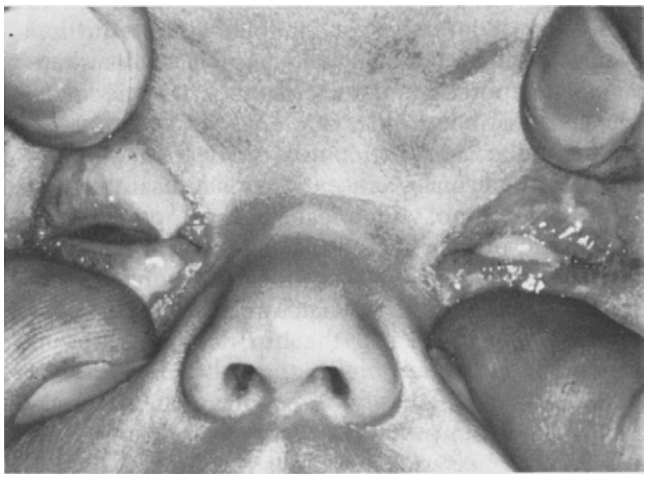

FIGURE 89-5 ■ Gonococcal ophthalmia neonatorum. The usual clinical finding is bilateral conjunctivitis that becomes progressively purulent if untreated. (From Gutman LT. Gonococcal infections. *Semin Pediatr Infect Dis* 2005;**16**:4.)

A presumptive diagnosis may be made by demonstrating typical gram-negative diplococci by Gram stain of conjunctival exudate. Because other organisms also may cause exudative infection of the conjunctivae, laboratory confirmation of the diagnosis of GON depends on culture results of *N. gonorrhoeae*.

Invasive disease rarely occurs in association with GON, but neonates with clinical evidence suggestive of GON should be evaluated for disseminated disease. The evaluation should include a thorough physical examination, especially of the joints. Exudate from the eyes or other sites of apparent local infection should be sent for Gram stain and culture on appropriate media.

Current recommendations in the United States are to obtain cultures of blood, eye discharge, and other potential sites of infection, such as CSF.[5] The absolute necessity of obtaining CSF for analysis and culture in otherwise well-appearing neonates is not certain, although it is reasonable to err on the side of caution. Neonates with GON generally should be hospitalized as part of initial management.

Gonococcal Scalp Abscess and Other Local Infections

Gonococcal infections of scalp wounds occur especially after fetal monitoring electrodes have been used on infants born to infected mothers.[102] The lesions may produce extensive local inflammatory disease and necrosis and can be a focus for disseminated infection. A scalp wound in a neonate should be cultured for gonococci, as
